

# Package ‘modelbased’

December 8, 2025

**Type** Package

**Title** Estimation of Model-Based Predictions, Contrasts and Means

**Version** 0.13.1

**Maintainer** Dominique Makowski <officialesystats@gmail.com>

**Description** Implements a general interface for model-based estimations for a wide variety of models, used in the computation of marginal means, contrast analysis and predictions. For a list of supported models, see 'insight::supported\_models()'.  
For a list of supported models, see 'insight::supported\_models()'.

**License** GPL-3

**URL** <https://easystats.github.io/modelbased/>

**BugReports** <https://github.com/easystats/modelbased/issues>

**Depends** R (>= 4.0)

**Imports** bayestestR (>= 0.17.0), datawizard (>= 1.3.0), insight (>= 1.4.3), parameters (>= 0.28.3), graphics, stats, tools, utils

**Suggests** afex, BH, betareg, boot, bootES, brglm2, brms, coda, collapse, correlation, coxme, curl, discovr, easystats, effectsize (>= 1.0.0), emmeans (>= 1.10.2), Formula, gamm4, gganimate, ggplot2, glmmTMB (>= 1.1.12), httr2, knitr, lme4, lmerTest, logspline, MASS, MatchIt, Matrix, marginalesffects (>= 0.29.0), mice, mgcv, mvtnorm, nanoparquet, nnet, ordinal, palmerpenguins, performance (>= 0.14.0), patchwork, pbkrtest, poorman, pscl, RcppEigen, Rdatasets, report, rmarkdown, rstanarm, rtdists, RWiener, sandwich, scales, see (>= 0.11.0), survival, testthat (>= 3.2.1), tinyplot (>= 0.6.0), tinytable, vdiff, withr

**VignetteBuilder** knitr

**Encoding** UTF-8

**Language** en-US

**RoxygenNote** 7.3.3

**Config/testthat/edition** 3

**Config/testthat/parallel** true

**Config/Needs/check** stan-dev/cmdstanr

**Config/Needs/website** easystats/easystatstemplate

**LazyData** true

**NeedsCompilation** no

---

as.data.frame.estimate\_contrasts

*Converting modelbased-objects into raw data frames*

---

## Description

as.data.frame() method for **modelbased** objects. Can be used to return a "raw" data frame without attributes and with standardized column names. By default, the original column names are preserved, to avoid unexpected changes, but this can be changed with the preserve\_names argument.

## Usage

```
## S3 method for class 'estimate_contrasts'
as.data.frame(
  x,
  row.names = NULL,
  optional = FALSE,
  ...,
  stringsAsFactors = FALSE,
  use_responsename = FALSE,
  preserve_names = TRUE
)
```

## Arguments

x	An object returned by the different estimate_*() functions.
row.names	NULL or a character vector giving the row names for the data frame. Missing values are not allowed.
optional	logical. If TRUE, setting row names and converting column names (to syntactic names: see <a href="#">make.names</a> ) is optional. Note that all of R's <b>base</b> package as.data.frame() methods use optional only for column names treatment, basically with the meaning of <a href="#">data.frame(*, check.names = !optional)</a> . See also the <a href="#">make.names</a> argument of the <a href="#">matrix</a> method.
...	Arguments passed to the data.frame method of as.data.frame().
stringsAsFactors	logical: should the character vector be converted to a factor?
use_responsename	Logical, if TRUE, the response variable name is used as column name for the estimate column (if available). If FALSE (default), the column is named "Coefficient".
preserve_names	Logical, if TRUE (default), the original column names are preserved. If FALSE, the estimate column is renamed to either the response name (if use_responsename = TRUE) or to "Coefficient".

## Value

A data frame.

**Examples**

```

model <- lm(Petal.Length ~ Species, data = iris)
out <- estimate_means(model, "Species")

# default
print(out)

as.data.frame(out)

as.data.frame(out, preserve_names = FALSE)

as.data.frame(out, preserve_names = FALSE, use_responsename = TRUE)

```

---

coffee\_data

*Sample dataset from a course about analysis of factorial designs*

---

**Description**

A sample data set from a course about the analysis of factorial designs, by Mattan S. Ben-Shachar. See following link for more information: <https://github.com/mattansb/Analysis-of-Factorial-Designs-foR-Psychologists>

The data consists of five variables from 120 observations:

- ID: A unique identifier for each participant
- sex: The participant's sex
- time: The time of day the participant was tested (morning, noon, or afternoon)
- coffee: Group indicator, whether participant drank coffee or not ("coffee" or "control").
- alertness: The participant's alertness score.

---

describe\_nonlinear

*Describe the smooth term (for GAMs) or non-linear predictors*

---

**Description**

This function summarises the smooth term trend in terms of linear segments. Using the approximate derivative, it separates a non-linear vector into quasi-linear segments (in which the trend is either positive or negative). Each of this segment its characterized by its beginning, end, size (in proportion, relative to the total size) trend (the linear regression coefficient) and linearity (the R2 of the linear regression).

**Usage**

```
describe_nonlinear(data, ...)

## S3 method for class 'data.frame'
describe_nonlinear(data, x = NULL, y = NULL, ...)

estimate_smooth(data, ...)
```

**Arguments**

data	The data containing the link, as for instance obtained by <code>estimate_relation()</code> .
...	Other arguments to be passed to or from.
x, y	The name of the responses variable (y) predicting variable (x).

**Value**

A data frame of linear description of non-linear terms.

**Examples**

```
# Create data
data <- data.frame(x = rnorm(200))
data$y <- data$x^2 + rnorm(200, 0, 0.5)

model <- lm(y ~ poly(x, 2), data = data)
link_data <- estimate_relation(model, length = 100)

describe_nonlinear(link_data, x = "x")
```

---

display.estimate\_contrasts

*Printing modelbased-objects*

---

**Description**

`print()` method for **modelbased** objects. Can be used to tweak the output of tables.

**Usage**

```
## S3 method for class 'estimate_contrasts'
display(
  object,
  select = NULL,
  include_grid = NULL,
  full_labels = NULL,
  format = "markdown",
```

```

    ...
)

## S3 method for class 'estimate_contrasts'
format(
  x,
  format = NULL,
  select = getOption("modelbased_select", NULL),
  include_grid = getOption("modelbased_include_grid", FALSE),
  ...
)

## S3 method for class 'estimate_contrasts'
print(x, select = NULL, include_grid = NULL, full_labels = NULL, ...)

```

## Arguments

- select** Determines which columns are printed and the table layout. There are two options for this argument:
- **A string expression with layout pattern**  
 select is a string with "tokens" enclosed in braces. These tokens will be replaced by their associated columns, where the selected columns will be collapsed into one column. Following tokens are replaced by the related coefficients or statistics: {estimate}, {se}, {ci} (or {ci\_low} and {ci\_high}), {p}, {pd} and {stars}. The token {ci} will be replaced by {ci\_low}, {ci\_high}. Example: select = "{estimate}{stars} ({ci})". It is possible to create multiple columns as well. A | separates values into new cells/columns. Example: select = "{estimate} ({ci})|{p}".
  - **A string indicating a pre-defined layout**  
 select can be one of the following string values, to create one of the following pre-defined column layouts:
    - "minimal": Estimates, confidence intervals and numeric p-values, in two columns. This is equivalent to select = "{estimate} ({ci})|{p}".
    - "short": Estimate, standard errors and numeric p-values, in two columns. This is equivalent to select = "{estimate} ({se})|{p}".
    - "ci": Estimates and confidence intervals, no asterisks for p-values. This is equivalent to select = "{estimate} ({ci})".
    - "se": Estimates and standard errors, no asterisks for p-values. This is equivalent to select = "{estimate} ({se})".
    - "ci\_p": Estimates, confidence intervals and asterisks for p-values. This is equivalent to select = "{estimate}{stars} ({ci})".
    - "se\_p": Estimates, standard errors and asterisks for p-values. This is equivalent to select = "{estimate}{stars} ({se})"..

Using select to define columns will re-order columns and remove all columns related to uncertainty (standard errors, confidence intervals), test statistics, and p-values (and similar, like pd or BF for Bayesian models), because these are assumed to be included or intentionally excluded when using select. The new

column order will be: Parameter columns first, followed by the "glue" columns, followed by all remaining columns. If further columns should also be placed first, add those as `focal_terms` attributes to `x`. I.e., following columns are considered as "parameter columns" and placed first: `c(easystats_columns("parameter"), attributes(x)$focal_terms)`.

**Note:** glue-like syntax is still experimental in the case of more complex models (like mixed models) and may not return expected results.

<code>include_grid</code>	Logical, if TRUE, the data grid is included in the table output. Only applies to prediction-functions like <code>estimate_relation()</code> or <code>estimate_link()</code> . Default is NULL, which will set the value based on <code>options(modelbased_include_grid)</code> , and use FALSE if no option is set.
<code>full_labels</code>	Logical, if TRUE (default), all labels for focal terms are shown. If FALSE, redundant (duplicated) labels are removed from rows. Default is NULL, which will set the value based on <code>options(modelbased_full_labels)</code> , and use TRUE if no option is set.
<code>format</code>	String, indicating the output format. Can be "markdown", "html", or "tt". <code>format = "html"</code> create a HTML table using the <code>gt</code> package. <code>format = "tt"</code> creates a <code>tinytable</code> object, which is either printed as markdown or HTML table, depending on the environment. See <code>insight::export_table()</code> for details.
<code>...</code>	Arguments passed to <code>insight::format_table()</code> or <code>insight::export_table()</code> .
<code>x, object</code>	An object returned by the different <code>estimate_*()</code> functions.

## Value

Invisibly returns `x`.

## Global Options to Customize Tables when Printing

Columns and table layout can be customized using `options()`:

- `modelbased_select`: `options(modelbased_select = <string>)` will set a default value for the `select` argument and can be used to define a custom default layout for printing.
- `modelbased_include_grid`: `options(modelbased_include_grid = TRUE)` will set a default value for the `include_grid` argument and can be used to include data grids in the output by default or not.
- `modelbased_full_labels`: `options(modelbased_full_labels = FALSE)` will remove redundant (duplicated) labels from rows.
- `easystats_display_format`: `options(easystats_display_format = <value>)` will set the default format for the `display()` methods. Can be one of "markdown", "html", or "tt".

## Note

Use `print_html()` and `print_md()` to create tables in HTML or markdown format, respectively.

**Examples**

```

model <- lm(Petal.Length ~ Species, data = iris)
out <- estimate_means(model, "Species")

# default
print(out)

# smaller set of columns
print(out, select = "minimal")

# remove redundant labels
data(efc, package = "modelbased")
efc <- datawizard::to_factor(efc, c("c161sex", "c172code", "e16sex"))
levels(efc$c172code) <- c("low", "mid", "high")
fit <- lm(neg_c_7 ~ c161sex * c172code * e16sex, data = efc)
out <- estimate_means(fit, c("c161sex", "c172code", "e16sex"))
print(out, full_labels = FALSE, select = "{estimate} ({se})")

```

---

efc *Sample dataset from the EFC Survey*

---

**Description**

Selected variables from the EUROFAMCARE survey. Useful when testing on "real-life" data sets, including random missing values. This data set also has value and variable label attributes.

---

estimate\_contrasts *Estimate Marginal Contrasts*

---

**Description**

Run a contrast analysis by estimating the differences between each level of a factor. See also other related functions such as [estimate\\_means\(\)](#) and [estimate\\_slopes\(\)](#).

**Usage**

```

estimate_contrasts(model, ...)

## Default S3 method:
estimate_contrasts(
  model,
  contrast = NULL,
  by = NULL,
  predict = NULL,
  ci = 0.95,

```

```

comparison = "pairwise",
estimate = NULL,
p_adjust = "none",
transform = NULL,
keep_iterations = FALSE,
effectsize = NULL,
iterations = 200,
es_type = NULL,
backend = NULL,
verbose = TRUE,
...
)

```

## Arguments

- |       |   |
|-------|---|
| model | A statistical model.  |
| ...   | <p>Other arguments passed, for instance, to <code>insight::get_datagrid()</code>, to functions from the <b>emmeans</b> or <b>marginaleffects</b> package, or to process Bayesian models via <code>bayestestR::describe_posterior()</code>. Examples:</p> <ul style="list-style-type: none"> <li>• <code>insight::get_datagrid()</code>: Argument such as <code>length</code>, <code>digits</code> or <code>range</code> can be used to control the (number of) representative values. For integer variables, <code>protect_integers</code> modulates whether these should also be treated as numerics, i.e. values can have fractions or not.</li> <li>• <b>marginaleffects</b>: Internally used functions are <code>avg_predictions()</code> for means and contrasts, and <code>avg_slope()</code> for slopes. Therefore, arguments for instance like <code>vcov</code>, <code>equivalence</code>, <code>df</code>, <code>slope</code>, <code>hypothesis</code> or even <code>newdata</code> can be passed to those functions. A <code>weights</code> argument is passed to the <code>wts</code> argument in <code>avg_predictions()</code> or <code>avg_slopes()</code>, however, weights can only be applied when <code>estimate</code> is "average" or "population" (i.e. for those marginalization options that do not use data grids). Other arguments, such as <code>re.form</code> or <code>allow.new.levels</code>, may be passed to <code>predict()</code> (which is internally used by <i>marginaleffects</i>) if supported by that model class.</li> <li>• <b>emmeans</b>: Internally used functions are <code>emmeans()</code> and <code>emtrends()</code>. Additional arguments can be passed to these functions.</li> <li>• Bayesian models: For Bayesian models, parameters are cleaned using <code>describe_posterior()</code>, thus, arguments like, for example, <code>centrality</code>, <code>rope_range</code>, or <code>test</code> are passed to that function.</li> <li>• Especially for <code>estimate_contrasts()</code> with integer focal predictors, for which contrasts should be calculated, use argument <code>integer_as_continuous</code> to set the maximum number of unique values in an integer predictor to treat that predictor as "discrete integer" or as numeric. For the first case, contrasts are calculated between values of the predictor, for the latter, contrasts of slopes are calculated. If the integer has more than <code>integer_as_continuous</code> unique values, it is treated as numeric. Defaults to 5. Set to TRUE to always treat integer predictors as continuous.</li> <li>• For count regression models that use an offset term, use <code>offset = &lt;value&gt;</code> to fix the offset at a specific value. Or use <code>estimate = "average"</code>, to average predictions over the distribution of the offset (if appropriate).</li> </ul> |

contrast	A character vector indicating the name of the variable(s) for which to compute the contrasts, optionally including representative values or levels at which contrasts are evaluated (e.g., <code>contrast="x=c('a', 'b')"</code> ).
by	The (focal) predictor variable(s) at which to evaluate the desired effect / mean / contrasts. Other predictors of the model that are not included here will be collapsed and "averaged" over (the effect will be estimated across them). <code>by</code> can be a character (vector) naming the focal predictors, optionally including representative values or levels at which focal predictors are evaluated (e.g., <code>by = "x = c(1, 2)"</code> ). When <code>estimate</code> is <i>not</i> "average", the <code>by</code> argument is used to create a "reference grid" or "data grid" with representative values for the focal predictors. In this case, <code>by</code> can also be list of named elements. See details in <a href="#">insight::get_datagrid()</a> to learn more about how to create data grids for predictors of interest.
predict	Is passed to the <code>type</code> argument in <code>emmeans::emmeans()</code> (when <code>backend = "emmeans"</code> ) or in <code>marginalEffects::avg_predictions()</code> (when <code>backend = "marginaleffects"</code> ). Valid options for <code>predict</code> are: <ul style="list-style-type: none"> <li>• <code>backend = "marginaleffects"</code>: <code>predict</code> can be "response", "link", "inverse_link" or any valid type option supported by model's class <code>predict()</code> method (e.g., for zero-inflation models from package <b>glmmTMB</b>, you can choose <code>predict = "zprob"</code> or <code>predict = "conditional"</code> etc., see <a href="#">glmmTMB::predict.glmmTMB</a>). By default, when <code>predict = NULL</code>, the most appropriate transformation is selected, which usually returns predictions or contrasts on the response-scale. The "inverse_link" is a special option, comparable to <i>marginaleffects</i>' <code>invlink(link)</code> option. It will calculate predictions on the link scale and then back-transform to the response scale.</li> <li>• <code>backend = "emmeans"</code>: <code>predict</code> can be "response", "link", "mu", "unlink", or "log". If <code>predict = NULL</code> (default), the most appropriate transformation is selected (which usually is "response"). See also <a href="#">this vignette</a>.</li> </ul> <p>See also section <i>Predictions on different scales</i>.</p>
ci	Confidence Interval (CI) level. Default to 0.95 (95%).
comparison	Specify the type of contrasts or tests that should be carried out. <ul style="list-style-type: none"> <li>• When <code>backend = "emmeans"</code>, can be one of "pairwise", "poly", "consec", "eff", "del.eff", "mean_chg", "trt.vs.ctrl", "dunnett", "wtcon" and some more. To test multiple hypotheses jointly (usually used for factorial designs), <code>comparison</code> can also be "joint". See also method argument in <a href="#">emmeans::contrast</a> and the <code>?emmeans::emmc</code>-functions.</li> <li>• For <code>backend = "marginaleffects"</code>, can be a numeric value, vector, or matrix, a string equation specifying the hypothesis to test, a string naming the comparison method, a formula, or a function. For options not described below, see documentation of <a href="#">marginaleffects::comparisons</a>, <a href="#">this website</a> and section <i>Comparison options</i> below. <ul style="list-style-type: none"> <li>– String: One of "pairwise", "reference", "sequential", "meandev", "meanotherdev", "poly", "helmert", or "trt_vs_ctrl". To test multiple hypotheses jointly (usually used for factorial designs), <code>comparison</code> can also be "joint". In this case, use the <code>test</code> argument to specify which test should be conducted: "F" (default) or "Chi2".</li> </ul> </li> </ul>

- String: Special string options are "inequality", "inequality\_ratio", and "inequality\_pairwise". `comparison = "inequality"` computes the marginal effect inequality summary of categorical predictors' overall effects, respectively, the comprehensive effect of an independent variable across all outcome categories of a nominal or ordinal dependent variable (also called *absolute inequality*, or total marginal effect, see *Mize and Han, 2025*). `"inequality_ratio"` computes the ratio of marginal effect inequality measures, also known as *relative inequality*. This is useful to compare the relative effects of different predictors on the dependent variable. It provides a measure of how much more or less inequality one predictor has compared to another. `comparison = "inequality_pairwise"` computes pairwise differences of absolute inequality measures, while `"inequality_ratio_pairwise"` computes pairwise differences of relative inequality measures (ratios). See an overview of applications in the related case study in the [vignettes](#).
- String equation: To identify parameters from the output, either specify the term name, or "b1", "b2" etc. to indicate rows, e.g.: "hp = drat", "b1 = b2", or "b1 + b2 + b3 = 0".
- Formula: A formula like `comparison ~ pairs | group`, where the left-hand side indicates the type of comparison (difference or ratio), the right-hand side determines the pairs of estimates to compare (reference, sequential, meandev, etc., see string-options). Optionally, comparisons can be carried out within subsets by indicating the grouping variable after a vertical bar ( | ).
- A custom function, e.g. `comparison = myfun`, or `comparison ~ I(my_fun(x)) | groups`.
- If contrasts should be calculated (or grouped by) factors, `comparison` can also be a matrix that specifies factor contrasts (see 'Examples').

## estimate

The `estimate` argument determines how predictions are averaged ("marginalized") over variables not specified in `by` or `contrast` (non-focal predictors). It controls whether predictions represent a "typical" individual, an "average" individual from the sample, or an "average" individual from a broader population.

- "typical" (Default): Calculates predictions for a balanced data grid representing all combinations of focal predictor levels (specified in `by`). For non-focal numeric predictors, it uses the mean; for non-focal categorical predictors, it marginalizes (averages) over the levels. This represents a "typical" observation based on the data grid and is useful for comparing groups. It answers: "What would the average outcome be for a 'typical' observation?". This is the default approach when estimating marginal means using the *emmeans* package.
- "average": Calculates predictions for each observation in the sample and then averages these predictions within each group defined by the focal predictors. This reflects the sample's actual distribution of non-focal predictors, not a balanced grid. It answers: "What is the predicted value for an average observation in my data?"
- "population": "Clones" each observation, creating copies with all possible combinations of focal predictor levels. It then averages the predic-

tions across these "counterfactual" observations (non-observed permutations) within each group. This extrapolates to a hypothetical broader population, considering "what if" scenarios. It answers: "What is the predicted response for the 'average' observation in a broader possible target population?" This approach entails more assumptions about the likelihood of different combinations, but can be more apt to generalize. This is also the option that should be used for **G-computation** (causal inference, see *Chatton and Rohrer 2024*). "counterfactual" is an alias for "population".

You can set a default option for the estimate argument via `options()`, e.g. `options(modelbased_estimate = "average")`.

Note following limitations:

- When you set estimate to "average", it calculates the average based only on the data points that actually exist. This is in particular important for two or more focal predictors, because it doesn't generate a *complete* grid of all theoretical combinations of predictor values. Consequently, the output may not include all the values.
- Filtering the output at values of continuous predictors, e.g. `by = "x=1:5"`, in combination with `estimate = "average"` may result in returning an empty data frame because of what was described above. In such case, you can use `estimate = "typical"` or use the `newdata` argument to provide a data grid of predictor values at which to evaluate predictions.
- `estimate = "population"` is not available for `estimate_slopes()`.

<code>p_adjust</code>	The p-values adjustment method for frequentist multiple comparisons. Can be one of "none" (default), "hochberg", "hommel", "bonferroni", "BH", "BY", "fdr", "tukey", "sidak", "sup-t", "esarey" or "holm". The "esarey" option is specifically for the case of Johnson-Neyman intervals, i.e. when calling <code>estimate_slopes()</code> with two numeric predictors in an interaction term. "sup-t" computes simultaneous confidence bands, also called sup-t confidence band (Montiel Olea & Plagborg-Møller, 2019). Details for the other options can be found in the p-value adjustment section of the <code>emmeans::test</code> documentation or <code>?stats::p.adjust</code> . Note that certain options provided by the <b>emmeans</b> package are only available if you set <code>backend = "emmeans"</code> .
<code>transform</code>	A function applied to predictions and confidence intervals to (back-) transform results, which can be useful in case the regression model has a transformed response variable (e.g., <code>lm(log(y) ~ x)</code> ). For Bayesian models, this function is applied to individual draws from the posterior distribution, before computing summaries. Can also be TRUE, in which case <code>insight::get_transformation()</code> is called to determine the appropriate transformation-function. Note that no standard errors are returned when transformations are applied.
<code>keep_iterations</code>	If TRUE, will keep all iterations (draws) of bootstrapped or Bayesian models. They will be added as additional columns named <code>iter_1</code> , <code>iter_2</code> , and so on. If <code>keep_iterations</code> is a positive number, only as many columns as indicated in <code>keep_iterations</code> will be added to the output. You can reshape them to a long format by running <code>bayestestR::reshape_iterations()</code> .
<code>effectsize</code>	Desired measure of standardized effect size, one of "emmeans", "marginal", or "boot". Default is NULL, i.e. no effect size will be computed.

iterations	The number of bootstrap resamples to perform.
es_type	Specifies the type of effect-size measure to estimate when using <code>effectsize = "boot"</code> . One of "unstandardized", "cohens.d", "hedges.g", "cohens.d.sigma", "r", or "akp.robust.d". See <code>effect.type</code> argument of <code>bootES::bootES()</code> for details. If not specified, defaults to "cohens.d".
backend	Whether to use "marginaleffects" (default) or "emmeans" as a backend. Results are usually very similar. The major difference will be found for mixed models, where <code>backend = "marginaleffects"</code> will also average across random effects levels, producing "marginal predictions" (instead of "conditional predictions", see Heiss 2022).  Another difference is that <code>backend = "marginaleffects"</code> will be slower than <code>backend = "emmeans"</code> . For most models, this difference is negligible. However, in particular complex models or large data sets fitted with <i>glmmTMB</i> can be significantly slower.  You can set a default backend via <code>options()</code> , e.g. use <code>options(modelbased_backend = "emmeans")</code> to use the <b>emmeans</b> package or <code>options(modelbased_backend = "marginaleffects")</code> to set <b>marginaleffects</b> as default backend.
verbose	Use FALSE to silence messages and warnings.

## Details

The `estimate_slopes()`, `estimate_means()` and `estimate_contrasts()` functions are forming a group, as they are all based on *marginal* estimations (estimations based on a model). All three are built on the **emmeans** or **marginaleffects** package (depending on the backend argument), so reading its documentation (for instance `emmeans::emmeans()`, `emmeans::emtrends()` or this [website](#)) is recommended to understand the idea behind these types of procedures.

- Model-based **predictions** is the basis for all that follows. Indeed, the first thing to understand is how models can be used to make predictions (see `estimate_relation()`). This corresponds to the predicted response (or "outcome variable") given specific predictor values of the predictors (i.e., given a specific data configuration). This is why the concept of the [reference grid](#) is so important for direct predictions.
- **Marginal "means"**, obtained via `estimate_means()`, are an extension of such predictions, allowing to "average" (collapse) some of the predictors, to obtain the average response value at a specific predictors configuration. This is typically used when some of the predictors of interest are factors. Indeed, the parameters of the model will usually give you the intercept value and then the "effect" of each factor level (how different it is from the intercept). Marginal means can be used to directly give you the mean value of the response variable at all the levels of a factor. Moreover, it can also be used to control, or average over predictors, which is useful in the case of multiple predictors with or without interactions.
- **Marginal contrasts**, obtained via `estimate_contrasts()`, are themselves an extension of marginal means, in that they allow to investigate the difference (i.e., the contrast) between the marginal means. This is, again, often used to get all pairwise differences between all levels of a factor. It works also for continuous predictors, for instance one could also be interested in whether the difference at two extremes of a continuous predictor is significant.
- Finally, **marginal effects**, obtained via `estimate_slopes()`, are different in that their focus is not values on the response variable, but the model's parameters. The idea is to assess the

effect of a predictor at a specific configuration of the other predictors. This is relevant in the case of interactions or non-linear relationships, when the effect of a predictor variable changes depending on the other predictors. Moreover, these effects can also be "averaged" over other predictors, to get for instance the "general trend" of a predictor over different factor levels.

**Example:** Let's imagine the following model  $\text{lm}(y \sim \text{condition} * x)$  where *condition* is a factor with 3 levels A, B and C and *x* a continuous variable (like age for example). One idea is to see how this model performs, and compare the actual response *y* to the one predicted by the model (using `estimate_expectation()`). Another idea is evaluate the average mean at each of the condition's levels (using `estimate_means()`), which can be useful to visualize them. Another possibility is to evaluate the difference between these levels (using `estimate_contrasts()`). Finally, one could also estimate the effect of *x* averaged over all conditions, or instead within each condition (using `estimate_slopes()`).

## Value

A data frame of estimated contrasts.

## Comparison options

- `comparison = "pairwise"`: This method computes all possible unique differences between pairs of levels of the focal predictor. For example, if a factor has levels A, B, and C, it would compute A-B, A-C, and B-C.
- `comparison = "reference"`: This compares each level of the focal predictor to a specified reference level (by default, the first level). For example, if levels are A, B, C, and A is the reference, it computes B-A and C-A.
- `comparison = "sequential"`: This compares each level to the one immediately following it in the factor's order. For levels A, B, C, it would compute B-A and C-B.
- `comparison = "meandev"`: This contrasts each level's estimate against the grand mean of all estimates for the focal predictor.
- `comparison = "meanotherdev"`: Similar to `meandev`, but each level's estimate is compared against the mean of all *other* levels, excluding itself.
- `comparison = "poly"`: These are used for ordered categorical variables to test for linear, quadratic, cubic, etc., trends across the levels. They assume equal spacing between levels.
- `comparison = "helmert"`: Contrast 2nd level to the first, 3rd to the average of the first two, and so on. Each level (except the first) is compared to the mean of the preceding levels. For levels A, B, C, it would compute B-A and  $C - (A+B)/2$ .
- `comparison = "trt_vs_ctrl"`: This compares all levels (excluding the first, which is typically the control) against the first level. It's often used when comparing multiple treatment groups to a single control group.
- To test multiple hypotheses jointly (usually used for factorial designs), `comparison` can also be `"joint"`. In this case, use the `test` argument to specify which test should be conducted: `"F"` (default) or `"Chi2"`.
- `comparison = "inequality"` computes the *absolute inequality* of groups, or in other words, the marginal effect inequality summary of categorical predictors' overall effects, respectively, the comprehensive effect of an independent variable across all outcome categories of a nominal or ordinal dependent variable (total marginal effect, see *Mize and Han, 2025*). The

marginal effect inequality focuses on the heterogeneity of the effects of a categorical *independent* variable. It helps understand how the effect of the variable differs across its categories or levels. When the *dependent* variable is categorical (e.g., logistic, ordinal or multinomial regression), marginal effect inequality provides a holistic view of how an independent variable affects a nominal or ordinal *dependent* variable. It summarizes the overall impact (absolute inequality, or total marginal effects) across all possible outcome categories.

- `comparison = "inequality_ratio"` is comparable to `comparison = "inequality"`, but instead of calculating the absolute inequality, it computes the *relative inequality* of groups. This is useful to compare the relative effects of different predictors on the dependent variable. It provides a measure of how much more or less inequality one predictor has compared to another.
- `comparison = "inequality_pairwise"` computes pairwise differences of absolute inequality measures, while `"inequality_ratio_pairwise"` computes pairwise differences of relative inequality measures (ratios). Depending on the sign, this measure indicates which of the predictors has a stronger impact on the dependent variable in terms of inequalities.

Examples for analysing inequalities are shown in the related [vignette](#).

## Effect Size

By default, `estimate_contrasts()` reports no standardized effect size on purpose. Should one request one, some things are to keep in mind. As the authors of *emmeans* write, "There is substantial disagreement among practitioners on what is the appropriate sigma to use in computing effect sizes; or, indeed, whether any effect-size measure is appropriate for some situations. The user is completely responsible for specifying appropriate parameters (or for failing to do so)."

In particular, effect size method "boot" does not correct for covariates in the model, so should probably only be used when there is just one categorical predictor (with however many levels). Some believe that if there are multiple predictors or any covariates, it is important to re-compute sigma adding back in the response variance associated with the variables that aren't part of the contrast.

`effectsize = "emmeans"` uses `emmeans::eff_size` with `sigma = stats::sigma(model)`, `edf = stats::df.residual(model)` and `method = "identity"`. This standardizes using the MSE (sigma). Some believe this works when the contrasts are the only predictors in the model, but not when there are covariates. The response variance accounted for by the covariates should not be removed from the SD used to standardize. Otherwise, *d* will be overestimated.

`effectsize = "marginal"` uses the following formula to compute effect size:  $d_{adj} \leftarrow \text{difference} * (1 - R^2) / \text{sigma}$ . This standardizes using the response SD with only the between-groups variance on the focal factor/contrast removed. This allows for groups to be equated on their covariates, but creates an appropriate scale for standardizing the response.

`effectsize = "boot"` uses bootstrapping (defaults to a low value of 200) through `bootES::bootES`. Adjusts for contrasts, but not for covariates.

## Predictions and contrasts at meaningful values (data grids)

To define representative values for focal predictors (specified in `by`, `contrast`, and `trend`), you can use several methods. These values are internally generated by `insight::get_datagrid()`, so consult its documentation for more details.

- You can directly specify values as strings or lists for `by`, `contrast`, and `trend`.
  - For numeric focal predictors, use examples like `by = "gear = c(4, 8)"`, `by = list(gear = c(4, 8))` or `by = "gear = 5:10"`
  - For factor or character predictors, use `by = "Species = c('setosa', 'virginica')"` or `by = list(Species = c('setosa', 'virginica'))`
- You can use "shortcuts" within square brackets, such as `by = "Sepal.Width = [sd]"` or `by = "Sepal.Width = [fivenum]"`
- For numeric focal predictors, if no representative values are specified (i.e., `by = "gear"` and *not* `by = "gear = c(4, 8)"`), `length` and `range` control the number and type of representative values for the focal predictors:
  - `length` determines how many equally spaced values are generated.
  - `range` specifies the type of values, like `"range"` or `"sd"`.
  - `length` and `range` apply to all numeric focal predictors.
  - If you have multiple numeric predictors, `length` and `range` can accept multiple elements, one for each predictor (see 'Examples').
- For integer variables, only values that appear in the data will be included in the data grid, independent from the `length` argument. This behaviour can be changed by setting `protect_integers = FALSE`, which will then treat integer variables as numerics (and possibly produce fractions).

See also [this vignette](#) for some examples.

### Predictions on different scales

The `predict` argument allows to generate predictions on different scales of the response variable. The `"link"` option does not apply to all models, and usually not to Gaussian models. `"link"` will leave the values on scale of the linear predictors. `"response"` (or `NULL`) will transform them on scale of the response variable. Thus for a logistic model, `"link"` will give estimations expressed in log-odds (probabilities on logit scale) and `"response"` in terms of probabilities.

To predict distributional parameters (called `"dpar"` in other packages), for instance when using complex formulae in `brms` models, the `predict` argument can take the value of the parameter you want to estimate, for instance `"sigma"`, `"kappa"`, etc.

`"response"` and `"inverse_link"` both return predictions on the response scale, however, `"response"` first calculates predictions on the response scale for each observation and *then* aggregates them by groups or levels defined in `by`. `"inverse_link"` first calculates predictions on the link scale for each observation, then aggregates them by groups or levels defined in `by`, and finally back-transforms the predictions to the response scale. Both approaches have advantages and disadvantages. `"response"` usually produces less biased predictions, but confidence intervals might be outside reasonable bounds (i.e., for instance can be negative for count data). The `"inverse_link"` approach is more robust in terms of confidence intervals, but might produce biased predictions. However, you can try to set `bias_correction = TRUE`, to adjust for this bias.

In particular for mixed models, using `"response"` is recommended, because averaging across random effects groups is then more accurate.

## Description

After fitting a model, it is useful generate model-based estimates of the response variables for different combinations of predictor values. Such estimates can be used to make inferences about **relationships** between variables, to make predictions about individual cases, or to compare the **predicted** values against the observed data.

The `modelbased` package includes 4 "related" functions, that mostly differ in their default arguments (in particular, `data` and `predict`):

- `estimate_prediction(data = NULL, predict = "prediction", ...)`
- `estimate_expectation(data = NULL, predict = "expectation", ...)`
- `estimate_relation(data = "grid", predict = "expectation", ...)`
- `estimate_link(data = "grid", predict = "link", ...)`

While they are all based on model-based predictions (using `insight::get_predicted()`), they differ in terms of the **type** of predictions they make by default. For instance, `estimate_prediction()` and `estimate_expectation()` return predictions for the original data used to fit the model, while `estimate_relation()` and `estimate_link()` return predictions on a `insight::get_datagrid()`. Similarly, `estimate_link` returns predictions on the link scale, while the others return predictions on the response scale. Note that the relevance of these differences depends on the model family (for instance, for linear models, `estimate_relation` is equivalent to `estimate_link()`, since there is no difference between the link-scale and the response scale).

Note that you can run `plot()` on the output of these functions to get some visual insights (see the [plotting examples](#)).

See the **details** section below for details about the different possibilities.

## Usage

```
estimate_expectation(
  model,
  data = NULL,
  by = NULL,
  predict = "expectation",
  ci = 0.95,
  transform = NULL,
  iterations = NULL,
  keep_iterations = FALSE,
  ...
)
```

```
estimate_link(
  model,
  data = "grid",
  by = NULL,
  predict = "link",
  ci = 0.95,
  transform = NULL,
  iterations = NULL,
```

```

    keep_iterations = FALSE,
    ...
  )

estimate_prediction(
  model,
  data = NULL,
  by = NULL,
  predict = "prediction",
  ci = 0.95,
  transform = NULL,
  iterations = NULL,
  keep_iterations = FALSE,
  ...
)

estimate_relation(
  model,
  data = "grid",
  by = NULL,
  predict = "expectation",
  ci = 0.95,
  transform = NULL,
  iterations = NULL,
  keep_iterations = FALSE,
  ...
)

```

### Arguments

model	A statistical model.
data	A data frame with model's predictors to estimate the response. If NULL, the model's data is used. If "grid", the model matrix is obtained (through <a href="#">insight::get_datagrid()</a> ).
by	The predictor variable(s) at which to estimate the response. Other predictors of the model that are not included here will be set to their mean value (for numeric predictors), reference level (for factors) or mode (other types). The by argument will be used to create a data grid via <a href="#">insight::get_datagrid()</a> , which will then be used as data argument. Thus, you cannot specify both data and by but only of these two arguments.
predict	This parameter controls what is predicted (and gets internally passed to <a href="#">insight::get_predicted()</a> ). In most cases, you don't need to care about it: it is changed automatically according to the different predicting functions (i.e., <a href="#">estimate_expectation()</a> , <a href="#">estimate_prediction()</a> , <a href="#">estimate_link()</a> or <a href="#">estimate_relation()</a> ). The only time you might be interested in manually changing it is to estimate other distributional parameters (called "dpar" in other packages) - for instance when using complex formulae in brms models. The predict argument can then be set to the parameter you want to estimate, for instance "sigma", "kappa", etc. Note that the distinction between "expectation", "link" and "prediction" does

	not then apply (as you are directly predicting the value of some distributional parameter), and the corresponding functions will then only differ in the default value of their data argument.
ci	Confidence Interval (CI) level. Default to 0.95 (95%).
transform	A function applied to predictions and confidence intervals to (back-) transform results, which can be useful in case the regression model has a transformed response variable (e.g., $\text{lm}(\log(y) \sim x)$ ). Can also be TRUE, in which case <code>insight::get_transformation()</code> is called to determine the appropriate transformation-function. Note that no standard errors are returned when transformations are applied.
iterations	For Bayesian models, this corresponds to the number of posterior draws. If NULL, will use all the draws (one for each iteration of the model). For frequentist models, if not NULL, will generate bootstrapped draws, from which bootstrapped CIs will be computed. Use <code>keep_iterations</code> to control if and how many draws will be included in the returned output (data frame), which can be used, for instance, for plotting.
keep_iterations	If TRUE, will keep all iterations (draws) of bootstrapped or Bayesian models. They will be added as additional columns named <code>iter_1</code> , <code>iter_2</code> , and so on. If <code>keep_iterations</code> is a positive number, only as many columns as indicated in <code>keep_iterations</code> will be added to the output. You can reshape them to a long format by running <code>bayestestR::reshape_iterations()</code> .
...	You can add all the additional control arguments from <code>insight::get_datagrid()</code> (used when <code>data = "grid"</code> ) and <code>insight::get_predicted()</code> . Furthermore, for count regression models that use an offset term, use <code>offset = &lt;value&gt;</code> to fix the offset at a specific value.

## Value

A data frame of predicted values and uncertainty intervals, with class "estimate\_predicted". Methods for `visualisation_recipe()` and `plot()` are available.

## Expected (average) values

The most important way that various types of response estimates differ is in terms of what quantity is being estimated and the meaning of the uncertainty intervals. The major choices are **expected values** for uncertainty in the regression line and **predicted values** for uncertainty in the individual case predictions.

**Expected values** refer to the fitted regression line - the estimated *average* response value (i.e., the "expectation") for individuals with specific predictor values. For example, in a linear model  $y = 2 + 3x + 4z + e$ , the estimated average  $y$  for individuals with  $x = 1$  and  $z = 2$  is 11.

For expected values, uncertainty intervals refer to uncertainty in the estimated **conditional average** (where might the true regression line actually fall)? Uncertainty intervals for expected values are also called "confidence intervals".

Expected values and their uncertainty intervals are useful for describing the relationship between variables and for describing how precisely a model has been estimated.

For generalized linear models, expected values are reported on one of two scales:

- The **link scale** refers to scale of the fitted regression line, after transformation by the link function. For example, for a logistic regression (logit binomial) model, the link scale gives expected log-odds. For a log-link Poisson model, the link scale gives the expected log-count.
- The **response scale** refers to the original scale of the response variable (i.e., without any link function transformation). Expected values on the link scale are back-transformed to the original response variable metric (e.g., expected probabilities for binomial models, expected counts for Poisson models).

### Individual case predictions

In contrast to expected values, **predicted values** refer to predictions for **individual cases**. Predicted values are also called "posterior predictions" or "posterior predictive draws".

For predicted values, uncertainty intervals refer to uncertainty in the **individual response values for each case** (where might any single case actually fall)? Uncertainty intervals for predicted values are also called "prediction intervals" or "posterior predictive intervals".

Predicted values and their uncertainty intervals are useful for forecasting the range of values that might be observed in new data, for making decisions about individual cases, and for checking if model predictions are reasonable ("posterior predictive checks").

Predicted values and intervals are always on the scale of the original response variable (not the link scale).

### Functions for estimating predicted values and uncertainty

*modelbased* provides 4 functions for generating model-based response estimates and their uncertainty:

- `estimate_expectation()`:
  - Generates **expected values** (conditional average) on the **response scale**.
  - The uncertainty interval is a *confidence interval*.
  - By default, values are computed using the data used to fit the model.
- `estimate_link()`:
  - Generates **expected values** (conditional average) on the **link scale**.
  - The uncertainty interval is a *confidence interval*.
  - By default, values are computed using a reference grid spanning the observed range of predictor values (see `insight::get_datagrid()`).
- `estimate_prediction()`:
  - Generates **predicted values** (for individual cases) on the **response scale**.
  - The uncertainty interval is a *prediction interval*.
  - By default, values are computed using the data used to fit the model.
- `estimate_relation()`:
  - Like `estimate_expectation()`.
  - Useful for visualizing a model.
  - Generates **expected values** (conditional average) on the **response scale**.
  - The uncertainty interval is a *confidence interval*.
  - By default, values are computed using a reference grid spanning the observed range of predictor values (see `insight::get_datagrid()`).

## Data for predictions

If the `data = NULL`, values are estimated using the data used to fit the model. If `data = "grid"`, values are computed using a reference grid spanning the observed range of predictor values with `insight::get_datagrid()`. This can be useful for model visualization. The number of predictor values used for each variable can be controlled with the `length` argument. `data` can also be a data frame containing columns with names matching the model frame (see `insight::get_data()`). This can be used to generate model predictions for specific combinations of predictor values.

## Finite mixture models

For finite mixture models (currently, only the `brms::mixture()` family from package *brms* is supported), use `predict = "classification"` with `data = NULL` to predict the class membership for each observation (e.g., `estimate_prediction(model, predict = "classification")`). To return predicted values stratified by class membership, use `predict = "link"` (possibly in combination with `data` or `by`, e.g. `estimate_link(model, by = "predictor")`). Other `predict` options will return predicted values of the outcome for the full data, not stratified by class membership.

## Note

These functions are built on top of `insight::get_predicted()` and correspond to different specifications of its parameters. It may be useful to read its [documentation](#), in particular the description of the `predict` argument for additional details on the difference between expected vs. predicted values and link vs. response scales.

Additional control parameters can be used to control results from `insight::get_datagrid()` (when `data = "grid"`) and from `insight::get_predicted()` (the function used internally to compute predictions).

For plotting, check the examples in `visualisation_recipe()`. Also check out the [Vignettes](#) and [README examples](#) for various examples, tutorials and usecases.

## Examples

```
library(modelbased)

# Linear Models
model <- lm(mpg ~ wt, data = mtcars)

# Get predicted and prediction interval (see insight::get_predicted)
estimate_expectation(model)

# Get expected values with confidence interval
pred <- estimate_relation(model)
pred

# Visualisation (see visualisation_recipe())
plot(pred)

# Standardize predictions
pred <- estimate_relation(lm(mpg ~ wt + am, data = mtcars))
z <- standardize(pred, include_response = FALSE)
```

```

z
unstandardize(z, include_response = FALSE)

# Logistic Models
model <- glm(vs ~ wt, data = mtcars, family = "binomial")
estimate_expectation(model)
estimate_relation(model)

# Mixed models
data(mtcars)
mtcars$gear <- as.factor(mtcars$gear)
model <- glmmTMB::glmmTMB(mpg ~ wt + (1 | gear), data = mtcars)
estimate_expectation(model)
estimate_relation(model)

# Predict random effects and calculate contrasts
estim <- estimate_relation(model, by = "gear")
estim

estimate_contrasts(estim)

# Bayesian models

model <- suppressWarnings(rstanarm::stan_glm(
  mpg ~ wt,
  data = mtcars, refresh = 0, iter = 200
))
estimate_expectation(model)
estimate_relation(model)

```

---

estimate\_grouplevel *Group-specific parameters of mixed models random effects*

---

## Description

Extract random parameters of each individual group in the context of mixed models, commonly referred to as BLUPs (Best Linear Unbiased Predictors). Can be reshaped to be of the same dimensions as the original data, which can be useful to add the random effects to the original data.

## Usage

```

estimate_grouplevel(model, ...)

## Default S3 method:
estimate_grouplevel(model, type = "random", ...)

## S3 method for class 'brmsfit'

```

```

estimate_grouplevel(
  model,
  type = "random",
  dispersion = TRUE,
  test = NULL,
  diagnostic = NULL,
  ...
)

reshape_grouplevel(x, ...)

## S3 method for class 'estimate_grouplevel'
reshape_grouplevel(x, indices = "all", group = NULL, ...)

```

### Arguments

model	A mixed model with random effects.
...	Other arguments passed to <code>parameters::model_parameters()</code> .
type	String, describing the type of estimates that should be returned. Can be "random", "total", or "marginal" (experimental). <ul style="list-style-type: none"> <li>• If "random" (default), the coefficients correspond to the conditional estimates of the random effects (as they are returned by <code>lme4::ranef()</code>). They typically correspond to the deviation of each individual group from their fixed effect (assuming the random effect is also included as a fixed effect). As such, a coefficient close to 0 means that the participants' effect is the same as the population-level effect (in other words, it is "in the norm").</li> <li>• If "total", it will return the sum of the random effect and its corresponding fixed effects, which internally relies on the <code>coef()</code> method (see <code>?coef.merMod</code>). Note that <code>type = "total"</code> yet does not return uncertainty indices (such as SE and CI) for models from <i>lme4</i> or <i>glmmTMB</i>, as the necessary information to compute them is not yet available. However, for Bayesian models, it is possible to compute them.</li> <li>• If "marginal" (experimental), it returns marginal group-levels estimates. The random intercepts are computed using marginal means (see <code>estimate_means()</code>), and the random slopes using marginal effects (see <code>estimate_slopes()</code>). This method does not directly extract the parameters estimated by the model, but recomputes them using model predictions. While this is more computationally intensive, one of the benefits include interpretability: the random intercepts correspond to the "mean" value of the outcome for each group, and the random slopes correspond to the direct average "effect" of the predictor for each random group. Note that in this case, the group-level estimates are not technically "intercepts" or model parameters, but marginal average levels and effects.</li> </ul>
dispersion, test, diagnostic	Arguments passed to <code>parameters::model_parameters()</code> for Bayesian models. By default, it won't return significance or diagnostic indices (as it is not typically very useful).

x	The output of <code>estimate_grouplevel()</code> .
indices	A character vector containing the indices (i.e., which columns) to extract (e.g., "Coefficient", "Median").
group	The name of the random factor to select as string value (e.g., "Participant", if the model was $y \sim x + (1 Participant)$ ).

### Details

Unlike raw group means, BLUPs apply shrinkage: they are a compromise between the group estimate and the population estimate. This improves generalizability and prevents overfitting.

### Examples

```
# lme4 model
data(mtcars)
model <- lme4::lmer(mpg ~ hp + (1 | carb), data = mtcars)
random <- estimate_grouplevel(model)

# Show group-specific effects
random

# Visualize random effects
plot(random)

# Reshape to wide data...
reshaped <- reshape_grouplevel(random, group = "carb", indices = c("Coefficient", "SE"))

# ...and can be easily combined with the original data
alldata <- merge(mtcars, reshaped)

# overall coefficients
estimate_grouplevel(model, type = "total")
```

---

estimate\_means

*Estimate Marginal Means (Model-based average at each factor level)*

---

### Description

Estimate average values of the response variable at each factor level or at representative values, respectively at values defined in a "data grid" or "reference grid". For plotting, check the examples in [visualisation\\_recipe\(\)](#). See also other related functions such as [estimate\\_contrasts\(\)](#) and [estimate\\_slopes\(\)](#).

**Usage**

```
estimate_means(
  model,
  by = "auto",
  predict = NULL,
  ci = 0.95,
  estimate = NULL,
  transform = NULL,
  keep_iterations = FALSE,
  backend = NULL,
  verbose = TRUE,
  ...
)
```

**Arguments**

model	A statistical model.
by	The (focal) predictor variable(s) at which to evaluate the desired effect / mean / contrasts. Other predictors of the model that are not included here will be collapsed and "averaged" over (the effect will be estimated across them). <code>by</code> can be a character (vector) naming the focal predictors, optionally including representative values or levels at which focal predictors are evaluated (e.g., <code>by = "x = c(1, 2)"</code> ). When <code>estimate</code> is <i>not</i> "average", the <code>by</code> argument is used to create a "reference grid" or "data grid" with representative values for the focal predictors. In this case, <code>by</code> can also be list of named elements. See details in <a href="#">insight::get_datagrid()</a> to learn more about how to create data grids for predictors of interest.
predict	Is passed to the <code>type</code> argument in <code>emmeans::emmeans()</code> (when <code>backend = "emmeans"</code> ) or in <code>marginalEffects::avg_predictions()</code> (when <code>backend = "marginalEffects"</code> ). Valid options for <code>predict</code> are: <ul style="list-style-type: none"> <li>• <code>backend = "marginalEffects"</code>: <code>predict</code> can be "response", "link", "inverse_link" or any valid type option supported by model's class <code>predict()</code> method (e.g., for zero-inflation models from package <b>glmmTMB</b>, you can choose <code>predict = "zprob"</code> or <code>predict = "conditional"</code> etc., see <a href="#">glmmTMB::predict.glmmTMB</a>). By default, when <code>predict = NULL</code>, the most appropriate transformation is selected, which usually returns predictions or contrasts on the response-scale. The "inverse_link" is a special option, comparable to <i>marginalEffects</i>' <code>invlink(link)</code> option. It will calculate predictions on the link scale and then back-transform to the response scale.</li> <li>• <code>backend = "emmeans"</code>: <code>predict</code> can be "response", "link", "mu", "unlink", or "log". If <code>predict = NULL</code> (default), the most appropriate transformation is selected (which usually is "response"). See also <a href="#">this vignette</a>.</li> </ul> See also section <i>Predictions on different scales</i> .
ci	Confidence Interval (CI) level. Default to 0.95 (95%).
estimate	The <code>estimate</code> argument determines how predictions are averaged ("marginalized") over variables not specified in <code>by</code> or <code>contrast</code> (non-focal predictors). It

controls whether predictions represent a "typical" individual, an "average" individual from the sample, or an "average" individual from a broader population.

- "typical" (Default): Calculates predictions for a balanced data grid representing all combinations of focal predictor levels (specified in `by`). For non-focal numeric predictors, it uses the mean; for non-focal categorical predictors, it marginalizes (averages) over the levels. This represents a "typical" observation based on the data grid and is useful for comparing groups. It answers: "What would the average outcome be for a 'typical' observation?". This is the default approach when estimating marginal means using the *emmeans* package.
- "average": Calculates predictions for each observation in the sample and then averages these predictions within each group defined by the focal predictors. This reflects the sample's actual distribution of non-focal predictors, not a balanced grid. It answers: "What is the predicted value for an average observation in my data?"
- "population": "Clones" each observation, creating copies with all possible combinations of focal predictor levels. It then averages the predictions across these "counterfactual" observations (non-observed permutations) within each group. This extrapolates to a hypothetical broader population, considering "what if" scenarios. It answers: "What is the predicted response for the 'average' observation in a broader possible target population?" This approach entails more assumptions about the likelihood of different combinations, but can be more apt to generalize. This is also the option that should be used for **G-computation** (causal inference, see *Chatton and Rohrer 2024*). "counterfactual" is an alias for "population".

You can set a default option for the `estimate` argument via `options()`, e.g. `options(modelbased_estimate = "average")`.

Note following limitations:

- When you set `estimate` to "average", it calculates the average based only on the data points that actually exist. This is in particular important for two or more focal predictors, because it doesn't generate a *complete* grid of all theoretical combinations of predictor values. Consequently, the output may not include all the values.
- Filtering the output at values of continuous predictors, e.g. `by = "x=1:5"`, in combination with `estimate = "average"` may result in returning an empty data frame because of what was described above. In such case, you can use `estimate = "typical"` or use the `newdata` argument to provide a data grid of predictor values at which to evaluate predictions.
- `estimate = "population"` is not available for `estimate_slopes()`.

`transform`

A function applied to predictions and confidence intervals to (back-) transform results, which can be useful in case the regression model has a transformed response variable (e.g.,  $\text{lm}(\log(y) \sim x)$ ). For Bayesian models, this function is applied to individual draws from the posterior distribution, before computing summaries. Can also be `TRUE`, in which case `insight::get_transformation()` is called to determine the appropriate transformation-function. Note that no standard errors are returned when transformations are applied.

keep_iterations	<p>If TRUE, will keep all iterations (draws) of bootstrapped or Bayesian models. They will be added as additional columns named <code>iter_1</code>, <code>iter_2</code>, and so on. If <code>keep_iterations</code> is a positive number, only as many columns as indicated in <code>keep_iterations</code> will be added to the output. You can reshape them to a long format by running <code>bayestestR::reshape_iterations()</code>.</p>
backend	<p>Whether to use "marginaleffects" (default) or "emmeans" as a backend. Results are usually very similar. The major difference will be found for mixed models, where <code>backend = "marginaleffects"</code> will also average across random effects levels, producing "marginal predictions" (instead of "conditional predictions", see Heiss 2022).</p> <p>Another difference is that <code>backend = "marginaleffects"</code> will be slower than <code>backend = "emmeans"</code>. For most models, this difference is negligible. However, in particular complex models or large data sets fitted with <i>glmmTMB</i> can be significantly slower.</p> <p>You can set a default backend via <code>options()</code>, e.g. use <code>options(modelbased_backend = "emmeans")</code> to use the <b>emmeans</b> package or <code>options(modelbased_backend = "marginaleffects")</code> to set <b>marginaleffects</b> as default backend.</p>
verbose	Use FALSE to silence messages and warnings.
...	<p>Other arguments passed, for instance, to <code>insight::get_datagrid()</code>, to functions from the <b>emmeans</b> or <b>marginaleffects</b> package, or to process Bayesian models via <code>bayestestR::describe_posterior()</code>. Examples:</p> <ul style="list-style-type: none"> <li>• <code>insight::get_datagrid()</code>: Argument such as <code>length</code>, <code>digits</code> or <code>range</code> can be used to control the (number of) representative values. For integer variables, <code>protect_integers</code> modulates whether these should also be treated as numerics, i.e. values can have fractions or not.</li> <li>• <b>marginaleffects</b>: Internally used functions are <code>avg_predictions()</code> for means and contrasts, and <code>avg_slope()</code> for slopes. Therefore, arguments for instance like <code>vcov</code>, <code>equivalence</code>, <code>df</code>, <code>slope</code>, <code>hypothesis</code> or even <code>newdata</code> can be passed to those functions. A <code>weights</code> argument is passed to the <code>wts</code> argument in <code>avg_predictions()</code> or <code>avg_slopes()</code>, however, <code>weights</code> can only be applied when <code>estimate</code> is "average" or "population" (i.e. for those marginalization options that do not use data grids). Other arguments, such as <code>re.form</code> or <code>allow.new.levels</code>, may be passed to <code>predict()</code> (which is internally used by <i>marginaleffects</i>) if supported by that model class.</li> <li>• <b>emmeans</b>: Internally used functions are <code>emmeans()</code> and <code>emtrends()</code>. Additional arguments can be passed to these functions.</li> <li>• Bayesian models: For Bayesian models, parameters are cleaned using <code>describe_posterior()</code>, thus, arguments like, for example, <code>centrality</code>, <code>rope_range</code>, or <code>test</code> are passed to that function.</li> <li>• Especially for <code>estimate_contrasts()</code> with integer focal predictors, for which contrasts should be calculated, use argument <code>integer_as_continuous</code> to set the maximum number of unique values in an integer predictor to treat that predictor as "discrete integer" or as numeric. For the first case, contrasts are calculated between values of the predictor, for the latter, contrasts of slopes are calculated. If the integer has more than <code>integer_as_continuous</code></li> </ul>

unique values, it is treated as numeric. Defaults to 5. Set to TRUE to always treat integer predictors as continuous.

- For count regression models that use an offset term, use `offset = <value>` to fix the offset at a specific value. Or use `estimate = "average"`, to average predictions over the distribution of the offset (if appropriate).

## Details

The `estimate_slopes()`, `estimate_means()` and `estimate_contrasts()` functions are forming a group, as they are all based on *marginal* estimations (estimations based on a model). All three are built on the **emmeans** or **marginaleffects** package (depending on the backend argument), so reading its documentation (for instance `emmeans::emmeans()`, `emmeans::emtrends()` or this [website](#)) is recommended to understand the idea behind these types of procedures.

- Model-based **predictions** is the basis for all that follows. Indeed, the first thing to understand is how models can be used to make predictions (see `estimate_relation()`). This corresponds to the predicted response (or "outcome variable") given specific predictor values of the predictors (i.e., given a specific data configuration). This is why the concept of the [reference grid](#) is so important for direct predictions.
- **Marginal "means"**, obtained via `estimate_means()`, are an extension of such predictions, allowing to "average" (collapse) some of the predictors, to obtain the average response value at a specific predictors configuration. This is typically used when some of the predictors of interest are factors. Indeed, the parameters of the model will usually give you the intercept value and then the "effect" of each factor level (how different it is from the intercept). Marginal means can be used to directly give you the mean value of the response variable at all the levels of a factor. Moreover, it can also be used to control, or average over predictors, which is useful in the case of multiple predictors with or without interactions.
- **Marginal contrasts**, obtained via `estimate_contrasts()`, are themselves an extension of marginal means, in that they allow to investigate the difference (i.e., the contrast) between the marginal means. This is, again, often used to get all pairwise differences between all levels of a factor. It works also for continuous predictors, for instance one could also be interested in whether the difference at two extremes of a continuous predictor is significant.
- Finally, **marginal effects**, obtained via `estimate_slopes()`, are different in that their focus is not values on the response variable, but the model's parameters. The idea is to assess the effect of a predictor at a specific configuration of the other predictors. This is relevant in the case of interactions or non-linear relationships, when the effect of a predictor variable changes depending on the other predictors. Moreover, these effects can also be "averaged" over other predictors, to get for instance the "general trend" of a predictor over different factor levels.

**Example:** Let's imagine the following model  $\text{lm}(y \sim \text{condition} * x)$  where *condition* is a factor with 3 levels A, B and C and *x* a continuous variable (like age for example). One idea is to see how this model performs, and compare the actual response *y* to the one predicted by the model (using `estimate_expectation()`). Another idea is evaluate the average mean at each of the condition's levels (using `estimate_means()`), which can be useful to visualize them. Another possibility is to evaluate the difference between these levels (using `estimate_contrasts()`). Finally, one could also estimate the effect of *x* averaged over all conditions, or instead within each condition (using `estimate_slopes()`).

**Value**

A data frame of estimated marginal means.

**Predictions and contrasts at meaningful values (data grids)**

To define representative values for focal predictors (specified in `by`, `contrast`, and `trend`), you can use several methods. These values are internally generated by `insight::get_datagrid()`, so consult its documentation for more details.

- You can directly specify values as strings or lists for `by`, `contrast`, and `trend`.
  - For numeric focal predictors, use examples like `by = "gear = c(4, 8)"`, `by = list(gear = c(4, 8))` or `by = "gear = 5:10"`
  - For factor or character predictors, use `by = "Species = c('setosa', 'virginica')"` or `by = list(Species = c('setosa', 'virginica'))`
- You can use "shortcuts" within square brackets, such as `by = "Sepal.Width = [sd]"` or `by = "Sepal.Width = [fivenum]"`
- For numeric focal predictors, if no representative values are specified (i.e., `by = "gear"` and *not* `by = "gear = c(4, 8)"`), `length` and `range` control the number and type of representative values for the focal predictors:
  - `length` determines how many equally spaced values are generated.
  - `range` specifies the type of values, like `"range"` or `"sd"`.
  - `length` and `range` apply to all numeric focal predictors.
  - If you have multiple numeric predictors, `length` and `range` can accept multiple elements, one for each predictor (see 'Examples').
- For integer variables, only values that appear in the data will be included in the data grid, independent from the `length` argument. This behaviour can be changed by setting `protect_integers = FALSE`, which will then treat integer variables as numerics (and possibly produce fractions).

See also [this vignette](#) for some examples.

**Predictions on different scales**

The `predict` argument allows to generate predictions on different scales of the response variable. The `"link"` option does not apply to all models, and usually not to Gaussian models. `"link"` will leave the values on scale of the linear predictors. `"response"` (or `NULL`) will transform them on scale of the response variable. Thus for a logistic model, `"link"` will give estimations expressed in log-odds (probabilities on logit scale) and `"response"` in terms of probabilities.

To predict distributional parameters (called `"dpar"` in other packages), for instance when using complex formulae in `brms` models, the `predict` argument can take the value of the parameter you want to estimate, for instance `"sigma"`, `"kappa"`, etc.

`"response"` and `"inverse_link"` both return predictions on the response scale, however, `"response"` first calculates predictions on the response scale for each observation and *then* aggregates them by groups or levels defined in `by`. `"inverse_link"` first calculates predictions on the link scale for each observation, then aggregates them by groups or levels defined in `by`, and finally back-transforms the predictions to the response scale. Both approaches have advantages and disadvantages. `"response"` usually produces less biased predictions, but confidence intervals might be

outside reasonable bounds (i.e., for instance can be negative for count data). The "inverse\_link" approach is more robust in terms of confidence intervals, but might produce biased predictions. However, you can try to set `bias_correction = TRUE`, to adjust for this bias.

In particular for mixed models, using "response" is recommended, because averaging across random effects groups is then more accurate.

### Finite mixture models

For finite mixture models (currently, only the `brms::mixture()` family from package *brms* is supported), use `predict = "link"` to return predicted values stratified by class membership. To predict the class membership, use `predict = "classification"`. See also [this vignette](#).

### Equivalence tests (smallest effect size of interest)

There are two ways of performing equivalence tests with **modelbased**.

- Using the *marginaleffects* machinery
 

The first is by specifying the equivalence argument. It takes a numeric vector of length two, defining the lower and upper bounds of the region of equivalence (ROPE). The output then includes an additional column `p_Equivalence`. A high p-value (non-significant result) means we reject the assumption of practical equivalence (and that a minimal important difference can be assumed, or that the estimate of the predicted value, slope or contrast is likely outside the ROPE).
- Using the `equivalence_test()` function
 

The second option is to use the `parameters::equivalence_test.lm()` function from the **parameters** package on the output of `estimate_means()`, `estimate_slopes()` or `estimate_contrasts()`. This method is more flexible and implements different "rules" to calculate practical equivalence. Furthermore, the rule decisions of accepting, rejecting, or undecided regarding the null hypothesis of the equivalence test are also provided. Thus, resulting p-values may differ from those p-values returned when using the equivalence argument.

The output from `equivalence_test()` returns a column `SGPV`, the "second generation p-value", which is equivalent to the `p (Equivalence)` column when using the equivalence argument. It is basically representative of the ROPE coverage from the confidence interval of the estimate (i.e. the proportion of the confidence intervals that lies within the region of practical equivalence).

### Global Options to Customize Estimation of Marginal Means

- `modelbased_backend`: `options(modelbased_backend = <string>)` will set a default value for the backend argument and can be used to set the package used by default to calculate marginal means. Can be "marginaleffects" or "emmeans".
- `modelbased_estimate`: `options(modelbased_estimate = <string>)` will set a default value for the estimate argument.
- `modelbased_integer`: `options(modelbased_integer = <value>)` will set the minimum number of unique values in an integer predictor to treat that predictor as a "discrete integer" or as continuous. If the integer has more than `modelbased_integer` unique values, it is treated as continuous. Set to `TRUE` to always treat integer predictors as continuous.

## Examples

```
library(modelbased)

# Frequentist models
# -----
model <- lm(Petal.Length ~ Sepal.Width * Species, data = iris)

estimate_means(model)

# the `length` argument is passed to `insight::get_datagrid()` and modulates
# the number of representative values to return for numeric predictors
estimate_means(model, by = c("Species", "Sepal.Width"), length = 2)

# an alternative way to setup your data grid is specify the values directly
estimate_means(model, by = c("Species", "Sepal.Width = c(2, 4)"))

# or use one of the many predefined "tokens" that help you creating a useful
# data grid - to learn more about creating data grids, see help in
# `?insight::get_datagrid`.
estimate_means(model, by = c("Species", "Sepal.Width = [fivenum]"))

## Not run:
# same for factors: filter by specific levels
estimate_means(model, by = "Species = c('versicolor', 'setosa')")
estimate_means(model, by = c("Species", "Sepal.Width = 0"))

# estimate marginal average of response at values for numeric predictor
estimate_means(model, by = "Sepal.Width", length = 5)
estimate_means(model, by = "Sepal.Width = c(2, 4)")

# or provide the definition of the data grid as list
estimate_means(
  model,
  by = list(Sepal.Width = c(2, 4), Species = c("versicolor", "setosa"))
)

# equivalence test: the null-hypothesis is that the estimate is outside
# the equivalence bounds [-4.5, 4.5]
estimate_means(model, by = "Species", equivalence = c(-4.5, 4.5))
```

```

# Methods that can be applied to it:
means <- estimate_means(model, by = c("Species", "Sepal.Width = 0"))

plot(means) # which runs visualisation_recipe()
standardize(means)

# grids for numeric predictors, combine range and length
model <- lm(Sepal.Length ~ Sepal.Width * Petal.Length, data = iris)

# create a "grid": value range for first numeric predictor, mean +/-1 SD
# for remaining numeric predictors.
estimate_means(model, c("Sepal.Width", "Petal.Length"), range = "grid")

# range from minimum to maximum spread over four values,
# and mean +/- 1 SD (a total of three values)
estimate_means(
  model,
  by = c("Sepal.Width", "Petal.Length"),
  range = c("range", "sd"),
  length = c(4, 3)
)

data <- iris
data$Petal.Length_factor <- ifelse(data$Petal.Length < 4.2, "A", "B")

model <- lme4::lmer(
  Petal.Length ~ Sepal.Width + Species + (1 | Petal.Length_factor),
  data = data
)
estimate_means(model)
estimate_means(model, by = "Sepal.Width", length = 3)

## End(Not run)

```

---

estimate\_slopes

*Estimate Marginal Effects*

---

## Description

Estimate the slopes (i.e., the coefficient) of a predictor over or within different factor levels, or alongside a numeric variable. In other words, to assess the effect of a predictor *at* specific configurations data. It corresponds to the derivative and can be useful to understand where a predictor has a significant role when interactions or non-linear relationships are present.

Other related functions based on marginal estimations includes [estimate\\_contrasts\(\)](#) and [estimate\\_means\(\)](#).

See the **Details** section below, and don't forget to also check out the [Vignettes](#) and [README examples](#) for various examples, tutorials and use cases.

**Usage**

```
estimate_slopes(
  model,
  trend = NULL,
  by = NULL,
  predict = NULL,
  ci = 0.95,
  estimate = NULL,
  transform = NULL,
  p_adjust = "none",
  keep_iterations = FALSE,
  backend = NULL,
  verbose = TRUE,
  ...
)
```

**Arguments**

model	A statistical model.
trend	A character indicating the name of the variable for which to compute the slopes. To get marginal effects at specific values, use <code>trend="&lt;variable&gt;"</code> along with the <code>by</code> argument, e.g. <code>by="&lt;variable&gt;=c(1, 3, 5)"</code> , or a combination of <code>by</code> and <code>length</code> , for instance, <code>by="&lt;variable&gt;", length=30</code> . To calculate average marginal effects over a range of values, use <code>trend="&lt;variable&gt;=seq(1, 3, 0.1)"</code> (or similar) and omit the variable provided in <code>trend</code> from the <code>by</code> argument.
by	The (focal) predictor variable(s) at which to evaluate the desired effect / mean / contrasts. Other predictors of the model that are not included here will be collapsed and "averaged" over (the effect will be estimated across them). <code>by</code> can be a character (vector) naming the focal predictors, optionally including representative values or levels at which focal predictors are evaluated (e.g., <code>by = "x = c(1, 2)"</code> ). When <code>estimate</code> is <i>not</i> "average", the <code>by</code> argument is used to create a "reference grid" or "data grid" with representative values for the focal predictors. In this case, <code>by</code> can also be list of named elements. See details in <a href="#">insight::get_datagrid()</a> to learn more about how to create data grids for predictors of interest.
predict	Is passed to the <code>type</code> argument in <code>emmeans::emmeans()</code> (when <code>backend = "emmeans"</code> ) or in <code>marginalEffects::avg_predictions()</code> (when <code>backend = "marginalEffects"</code> ). Valid options for <code>predict</code> are: <ul style="list-style-type: none"> <li><code>backend = "marginalEffects"</code>: <code>predict</code> can be "response", "link", "inverse_link" or any valid type option supported by model's class <code>predict()</code> method (e.g., for zero-inflation models from package <b>glmmTMB</b>, you can choose <code>predict = "zprob"</code> or <code>predict = "conditional"</code> etc., see <a href="#">glmmTMB::predict.glmmTMB</a>). By default, when <code>predict = NULL</code>, the most appropriate transformation is selected, which usually returns predictions or contrasts on the response-scale. The "inverse_link" is a special option, comparable to <i>marginalEffects</i>' <code>invlink(link)</code> option. It will calculate predictions on the link scale</li> </ul>

and then back-transform to the response scale.

- `backend = "emmeans"`: predict can be "response", "link", "mu", "unlink", or "log". If `predict = NULL` (default), the most appropriate transformation is selected (which usually is "response"). See also [this vignette](#).

See also section *Predictions on different scales*.

ci

Confidence Interval (CI) level. Default to 0.95 (95%).

estimate

The `estimate` argument determines how predictions are averaged ("marginalized") over variables not specified in `by` or `contrast` (non-focal predictors). It controls whether predictions represent a "typical" individual, an "average" individual from the sample, or an "average" individual from a broader population.

- "typical" (Default): Calculates predictions for a balanced data grid representing all combinations of focal predictor levels (specified in `by`). For non-focal numeric predictors, it uses the mean; for non-focal categorical predictors, it marginalizes (averages) over the levels. This represents a "typical" observation based on the data grid and is useful for comparing groups. It answers: "What would the average outcome be for a 'typical' observation?". This is the default approach when estimating marginal means using the *emmeans* package.
- "average": Calculates predictions for each observation in the sample and then averages these predictions within each group defined by the focal predictors. This reflects the sample's actual distribution of non-focal predictors, not a balanced grid. It answers: "What is the predicted value for an average observation in my data?"
- "population": "Clones" each observation, creating copies with all possible combinations of focal predictor levels. It then averages the predictions across these "counterfactual" observations (non-observed permutations) within each group. This extrapolates to a hypothetical broader population, considering "what if" scenarios. It answers: "What is the predicted response for the 'average' observation in a broader possible target population?" This approach entails more assumptions about the likelihood of different combinations, but can be more apt to generalize. This is also the option that should be used for **G-computation** (causal inference, see *Chatton and Rohrer 2024*). "counterfactual" is an alias for "population".

You can set a default option for the `estimate` argument via `options()`, e.g. `options(modelbased_estimate = "average")`.

Note following limitations:

- When you set `estimate` to "average", it calculates the average based only on the data points that actually exist. This is in particular important for two or more focal predictors, because it doesn't generate a *complete* grid of all theoretical combinations of predictor values. Consequently, the output may not include all the values.
- Filtering the output at values of continuous predictors, e.g. `by = "x=1:5"`, in combination with `estimate = "average"` may result in returning an empty data frame because of what was described above. In such case, you can use `estimate = "typical"` or use the `newdata` argument to provide a data grid of predictor values at which to evaluate predictions.

	<ul style="list-style-type: none"> <li>• <code>estimate = "population"</code> is not available for <code>estimate_slopes()</code>.</li> </ul>
<code>transform</code>	A function applied to predictions and confidence intervals to (back-) transform results, which can be useful in case the regression model has a transformed response variable (e.g., <code>lm(log(y) ~ x)</code> ). For Bayesian models, this function is applied to individual draws from the posterior distribution, before computing summaries. Can also be <code>TRUE</code> , in which case <code>insight::get_transformation()</code> is called to determine the appropriate transformation-function. Note that no standard errors are returned when transformations are applied.
<code>p_adjust</code>	The p-values adjustment method for frequentist multiple comparisons. For <code>estimate_slopes()</code> , multiple comparison only occurs for Johnson-Neyman intervals, i.e. in case of interactions with two numeric predictors (one specified in <code>trend</code> , one in <code>by</code> ). In this case, the <code>"esarey"</code> or <code>"sup-t"</code> options are recommended, but <code>p_adjust</code> can also be one of <code>"none"</code> (default), <code>"hochberg"</code> , <code>"hommel"</code> , <code>"bonferroni"</code> , <code>"BH"</code> , <code>"BY"</code> , <code>"fdr"</code> , <code>"tukey"</code> , <code>"sidak"</code> , or <code>"holm"</code> . <code>"sup-t"</code> computes simultaneous confidence bands, also called sup-t confidence band (Montiel Olea & Plagborg-Møller, 2019).
<code>keep_iterations</code>	If <code>TRUE</code> , will keep all iterations (draws) of bootstrapped or Bayesian models. They will be added as additional columns named <code>iter_1</code> , <code>iter_2</code> , and so on. If <code>keep_iterations</code> is a positive number, only as many columns as indicated in <code>keep_iterations</code> will be added to the output. You can reshape them to a long format by running <code>bayestestR::reshape_iterations()</code> .
<code>backend</code>	<p>Whether to use <code>"marginaleffects"</code> (default) or <code>"emmeans"</code> as a backend. Results are usually very similar. The major difference will be found for mixed models, where <code>backend = "marginaleffects"</code> will also average across random effects levels, producing "marginal predictions" (instead of "conditional predictions", see Heiss 2022).</p> <p>Another difference is that <code>backend = "marginaleffects"</code> will be slower than <code>backend = "emmeans"</code>. For most models, this difference is negligible. However, in particular complex models or large data sets fitted with <code>glmmTMB</code> can be significantly slower.</p> <p>You can set a default backend via <code>options()</code>, e.g. use <code>options(modelbased_backend = "emmeans")</code> to use the <b>emmeans</b> package or <code>options(modelbased_backend = "marginaleffects")</code> to set <b>marginaleffects</b> as default backend.</p>
<code>verbose</code>	Use <code>FALSE</code> to silence messages and warnings.
<code>...</code>	<p>Other arguments passed, for instance, to <code>insight::get_datagrid()</code>, to functions from the <b>emmeans</b> or <b>marginaleffects</b> package, or to process Bayesian models via <code>bayestestR::describe_posterior()</code>. Examples:</p> <ul style="list-style-type: none"> <li>• <code>insight::get_datagrid()</code>: Argument such as <code>length</code>, <code>digits</code> or <code>range</code> can be used to control the (number of) representative values. For integer variables, <code>protect_integers</code> modulates whether these should also be treated as numerics, i.e. values can have fractions or not.</li> <li>• <b>marginaleffects</b>: Internally used functions are <code>avg_predictions()</code> for means and contrasts, and <code>avg_slope()</code> for slopes. Therefore, arguments for instance like <code>vcov</code>, <code>equivalence</code>, <code>df</code>, <code>slope</code>, <code>hypothesis</code> or even <code>newdata</code> can be passed to those functions. A <code>weights</code> argument is passed to the <code>wt</code>s</li> </ul>

argument in `avg_predictions()` or `avg_slopes()`, however, weights can only be applied when `estimate` is "average" or "population" (i.e. for those marginalization options that do not use data grids). Other arguments, such as `re.form` or `allow.new.levels`, may be passed to `predict()` (which is internally used by *marginalEffects*) if supported by that model class.

- **emmeans**: Internally used functions are `emmeans()` and `emtrends()`. Additional arguments can be passed to these functions.
- Bayesian models: For Bayesian models, parameters are cleaned using `describe_posterior()`, thus, arguments like, for example, `centrality`, `rope_range`, or `test` are passed to that function.
- Especially for `estimate_contrasts()` with integer focal predictors, for which contrasts should be calculated, use argument `integer_as_continuous` to set the maximum number of unique values in an integer predictor to treat that predictor as "discrete integer" or as numeric. For the first case, contrasts are calculated between values of the predictor, for the latter, contrasts of slopes are calculated. If the integer has more than `integer_as_continuous` unique values, it is treated as numeric. Defaults to 5. Set to TRUE to always treat integer predictors as continuous.
- For count regression models that use an offset term, use `offset = <value>` to fix the offset at a specific value. Or use `estimate = "average"`, to average predictions over the distribution of the offset (if appropriate).

## Details

The `estimate_slopes()`, `estimate_means()` and `estimate_contrasts()` functions are forming a group, as they are all based on *marginal* estimations (estimations based on a model). All three are built on the **emmeans** or **marginalEffects** package (depending on the backend argument), so reading its documentation (for instance `emmeans::emmeans()`, `emmeans::emtrends()` or this [website](#)) is recommended to understand the idea behind these types of procedures.

- Model-based **predictions** is the basis for all that follows. Indeed, the first thing to understand is how models can be used to make predictions (see `estimate_relation()`). This corresponds to the predicted response (or "outcome variable") given specific predictor values of the predictors (i.e., given a specific data configuration). This is why the concept of the [reference grid](#) is so important for direct predictions.
- **Marginal "means"**, obtained via `estimate_means()`, are an extension of such predictions, allowing to "average" (collapse) some of the predictors, to obtain the average response value at a specific predictors configuration. This is typically used when some of the predictors of interest are factors. Indeed, the parameters of the model will usually give you the intercept value and then the "effect" of each factor level (how different it is from the intercept). Marginal means can be used to directly give you the mean value of the response variable at all the levels of a factor. Moreover, it can also be used to control, or average over predictors, which is useful in the case of multiple predictors with or without interactions.
- **Marginal contrasts**, obtained via `estimate_contrasts()`, are themselves an extension of marginal means, in that they allow to investigate the difference (i.e., the contrast) between the marginal means. This is, again, often used to get all pairwise differences between all levels of a factor. It works also for continuous predictors, for instance one could also be interested in whether the difference at two extremes of a continuous predictor is significant.

- Finally, **marginal effects**, obtained via `estimate_slopes()`, are different in that their focus is not values on the response variable, but the model's parameters. The idea is to assess the effect of a predictor at a specific configuration of the other predictors. This is relevant in the case of interactions or non-linear relationships, when the effect of a predictor variable changes depending on the other predictors. Moreover, these effects can also be "averaged" over other predictors, to get for instance the "general trend" of a predictor over different factor levels.

**Example:** Let's imagine the following model  $\text{lm}(y \sim \text{condition} * x)$  where `condition` is a factor with 3 levels A, B and C and `x` a continuous variable (like age for example). One idea is to see how this model performs, and compare the actual response `y` to the one predicted by the model (using `estimate_expectation()`). Another idea is evaluate the average mean at each of the condition's levels (using `estimate_means()`), which can be useful to visualize them. Another possibility is to evaluate the difference between these levels (using `estimate_contrasts()`). Finally, one could also estimate the effect of `x` averaged over all conditions, or instead within each condition (using `estimate_slopes()`).

## Value

A data.frame of class `estimate_slopes`.

## Predictions and contrasts at meaningful values (data grids)

To define representative values for focal predictors (specified in `by`, `contrast`, and `trend`), you can use several methods. These values are internally generated by `insight::get_datagrid()`, so consult its documentation for more details.

- You can directly specify values as strings or lists for `by`, `contrast`, and `trend`.
  - For numeric focal predictors, use examples like `by = "gear = c(4, 8)"`, `by = list(gear = c(4, 8))` or `by = "gear = 5:10"`
  - For factor or character predictors, use `by = "Species = c('setosa', 'virginica')"` or `by = list(Species = c('setosa', 'virginica'))`
- You can use "shortcuts" within square brackets, such as `by = "Sepal.Width = [sd]"` or `by = "Sepal.Width = [fivenum]"`
- For numeric focal predictors, if no representative values are specified (i.e., `by = "gear"` and *not* `by = "gear = c(4, 8)"`), `length` and `range` control the number and type of representative values for the focal predictors:
  - `length` determines how many equally spaced values are generated.
  - `range` specifies the type of values, like `"range"` or `"sd"`.
  - `length` and `range` apply to all numeric focal predictors.
  - If you have multiple numeric predictors, `length` and `range` can accept multiple elements, one for each predictor (see 'Examples').
- For integer variables, only values that appear in the data will be included in the data grid, independent from the `length` argument. This behaviour can be changed by setting `protect_integers = FALSE`, which will then treat integer variables as numerics (and possibly produce fractions).

See also [this vignette](#) for some examples.

## End(Not run)

```

---

fish

*Sample data set*

---

## Description

A sample data set, used in tests and some examples. Useful for demonstrating count models (with or without zero-inflation component). It consists of nine variables from 250 observations.

---

get\_emcontrasts

*Consistent API for 'emmeans' and 'marginaleffects'*

---

## Description

These functions are convenient wrappers around the **emmeans** and the **marginaleffects** packages. They are mostly available for developers who want to leverage a unified API for getting model-based estimates, and regular users should use the `estimate_*` set of functions.

The `get_emmeans()`, `get_emcontrasts()` and `get_emptrends()` functions are wrappers around `emmeans::emmeans()` and `emmeans::emptrends()`.

## Usage

```
get_emcontrasts(  
  model,  
  contrast = NULL,  
  by = NULL,  
  predict = NULL,  
  comparison = "pairwise",  
  keep_iterations = FALSE,  
  verbose = TRUE,  
  ...  
)
```

```
get_emmeans(  
  model,  
  by = "auto",  
  predict = NULL,  
  keep_iterations = FALSE,  
  verbose = TRUE,  
  ...  
)
```

```
get_emptrends(  
  model,  
  trend = NULL,  
  by = NULL,  
  predict = NULL,  
  keep_iterations = FALSE,  
  verbose = TRUE,  
  ...  
)
```

```
get_marginalcontrasts(  
  model,  
  contrast = NULL,  
  by = NULL,  
  predict = NULL,  
  ci = 0.95,  
  comparison = "pairwise",  
  estimate = NULL,  
  transform = NULL,
```

```

    p_adjust = "none",
    keep_iterations = FALSE,
    verbose = TRUE,
    ...
)

get_marginalmeans(
  model,
  by = "auto",
  predict = NULL,
  ci = 0.95,
  estimate = NULL,
  transform = NULL,
  keep_iterations = FALSE,
  verbose = TRUE,
  ...
)

get_marginaltrends(
  model,
  trend = NULL,
  by = NULL,
  predict = NULL,
  ci = 0.95,
  estimate = NULL,
  transform = NULL,
  p_adjust = "none",
  keep_iterations = FALSE,
  verbose = TRUE,
  ...
)

```

## Arguments

model	A statistical model.
contrast	A character vector indicating the name of the variable(s) for which to compute the contrasts, optionally including representative values or levels at which contrasts are evaluated (e.g., <code>contrast="x=c('a', 'b')"</code> ).
by	The (focal) predictor variable(s) at which to evaluate the desired effect / mean / contrasts. Other predictors of the model that are not included here will be collapsed and "averaged" over (the effect will be estimated across them). <code>by</code> can be a character (vector) naming the focal predictors, optionally including representative values or levels at which focal predictors are evaluated (e.g., <code>by = "x = c(1, 2)"</code> ). When <code>estimate</code> is <i>not</i> "average", the <code>by</code> argument is used to create a "reference grid" or "data grid" with representative values for the focal predictors. In this case, <code>by</code> can also be list of named elements. See details in <a href="#">insight::get_datagrid()</a> to learn more about how to create data grids for predictors of interest.

predict	<p>Is passed to the type argument in <code>emmeans::emmeans()</code> (when <code>backend = "emmeans"</code>) or in <code>marginaleffects::avg_predictions()</code> (when <code>backend = "marginaleffects"</code>). Valid options for <code>predict</code> are:</p> <ul style="list-style-type: none"> <li>• <code>backend = "marginaleffects"</code>: <code>predict</code> can be <code>"response"</code>, <code>"link"</code>, <code>"inverse_link"</code> or any valid type option supported by model's class <code>predict()</code> method (e.g., for zero-inflation models from package <b>glmmTMB</b>, you can choose <code>predict = "zprob"</code> or <code>predict = "conditional"</code> etc., see <a href="#">glmmTMB::predict.glmmTMB</a>). By default, when <code>predict = NULL</code>, the most appropriate transformation is selected, which usually returns predictions or contrasts on the response-scale. The <code>"inverse_link"</code> is a special option, comparable to <i>marginaleffects</i>' <code>invlink(link)</code> option. It will calculate predictions on the link scale and then back-transform to the response scale.</li> <li>• <code>backend = "emmeans"</code>: <code>predict</code> can be <code>"response"</code>, <code>"link"</code>, <code>"mu"</code>, <code>"unlink"</code>, or <code>"log"</code>. If <code>predict = NULL</code> (default), the most appropriate transformation is selected (which usually is <code>"response"</code>). See also <a href="#">this vignette</a>.</li> </ul> <p>See also section <i>Predictions on different scales</i>.</p>
comparison	<p>Specify the type of contrasts or tests that should be carried out.</p> <ul style="list-style-type: none"> <li>• When <code>backend = "emmeans"</code>, can be one of <code>"pairwise"</code>, <code>"poly"</code>, <code>"consec"</code>, <code>"eff"</code>, <code>"del.eff"</code>, <code>"mean_chg"</code>, <code>"trt.vs.ctrl"</code>, <code>"dunnett"</code>, <code>"wtcon"</code> and some more. To test multiple hypotheses jointly (usually used for factorial designs), <code>comparison</code> can also be <code>"joint"</code>. See also method argument in <a href="#">emmeans::contrast</a> and the <code>?emmeans::emmc-functions</code>.</li> <li>• For <code>backend = "marginaleffects"</code>, can be a numeric value, vector, or matrix, a string equation specifying the hypothesis to test, a string naming the comparison method, a formula, or a function. For options not described below, see documentation of <a href="#">marginaleffects::comparisons</a>, <a href="#">this website</a> and section <i>Comparison options</i> below. <ul style="list-style-type: none"> <li>– String: One of <code>"pairwise"</code>, <code>"reference"</code>, <code>"sequential"</code>, <code>"meandev"</code>, <code>"meanotherdev"</code>, <code>"poly"</code>, <code>"helmert"</code>, or <code>"trt_vs_ctrl"</code>. To test multiple hypotheses jointly (usually used for factorial designs), <code>comparison</code> can also be <code>"joint"</code>. In this case, use the <code>test</code> argument to specify which test should be conducted: <code>"F"</code> (default) or <code>"Chi2"</code>.</li> <li>– String: Special string options are <code>"inequality"</code>, <code>"inequality_ratio"</code>, and <code>"inequality_pairwise"</code>. <code>comparison = "inequality"</code> computes the marginal effect inequality summary of categorical predictors' overall effects, respectively, the comprehensive effect of an independent variable across all outcome categories of a nominal or ordinal dependent variable (also called <i>absolute inequality</i>, or total marginal effect, see <i>Mize and Han, 2025</i>). <code>"inequality_ratio"</code> computes the ratio of marginal effect inequality measures, also known as <i>relative inequality</i>. This is useful to compare the relative effects of different predictors on the dependent variable. It provides a measure of how much more or less inequality one predictor has compared to another. <code>comparison = "inequality_pairwise"</code> computes pairwise differences of absolute inequality measures, while <code>"inequality_ratio_pairwise"</code> computes pairwise differences of relative inequality measures (ratios). See an overview of applications in the related case study in the <a href="#">vignettes</a>.</li> </ul> </li> </ul>

- String equation: To identify parameters from the output, either specify the term name, or "b1", "b2" etc. to indicate rows, e.g.: "hp = drat", "b1 = b2", or "b1 + b2 + b3 = 0".
- Formula: A formula like comparison ~ pairs | group, where the left-hand side indicates the type of comparison (difference or ratio), the right-hand side determines the pairs of estimates to compare (reference, sequential, meandev, etc., see string-options). Optionally, comparisons can be carried out within subsets by indicating the grouping variable after a vertical bar ( | ).
- A custom function, e.g. comparison = myfun, or comparison ~ I(my\_fun(x)) | groups.
- If contrasts should be calculated (or grouped by) factors, comparison can also be a matrix that specifies factor contrasts (see 'Examples').

keep\_iterations

If TRUE, will keep all iterations (draws) of bootstrapped or Bayesian models. They will be added as additional columns named iter\_1, iter\_2, and so on. If keep\_iterations is a positive number, only as many columns as indicated in keep\_iterations will be added to the output. You can reshape them to a long format by running `bayestestR::reshape_iterations()`.

verbose

Use FALSE to silence messages and warnings.

...

Other arguments passed, for instance, to `insight::get_datagrid()`, to functions from the **emmeans** or **marginaleffects** package, or to process Bayesian models via `bayestestR::describe_posterior()`. Examples:

- `insight::get_datagrid()`: Argument such as length, digits or range can be used to control the (number of) representative values. For integer variables, `protect_integers` modulates whether these should also be treated as numerics, i.e. values can have fractions or not.
- **marginaleffects**: Internally used functions are `avg_predictions()` for means and contrasts, and `avg_slope()` for slopes. Therefore, arguments for instance like `vcov`, `equivalence`, `df`, `slope`, `hypothesis` or even `newdata` can be passed to those functions. A `weights` argument is passed to the `wts` argument in `avg_predictions()` or `avg_slopes()`, however, weights can only be applied when estimate is "average" or "population" (i.e. for those marginalization options that do not use data grids). Other arguments, such as `re.form` or `allow.new.levels`, may be passed to `predict()` (which is internally used by `marginaleffects`) if supported by that model class.
- **emmeans**: Internally used functions are `emmeans()` and `emtrends()`. Additional arguments can be passed to these functions.
- Bayesian models: For Bayesian models, parameters are cleaned using `describe_posterior()`, thus, arguments like, for example, `centrality`, `rope_range`, or `test` are passed to that function.
- Especially for `estimate_contrasts()` with integer focal predictors, for which contrasts should be calculated, use argument `integer_as_continuous` to set the maximum number of unique values in an integer predictor to treat that predictor as "discrete integer" or as numeric. For the first case, contrasts are calculated between values of the predictor, for the latter, contrasts of

slopes are calculated. If the integer has more than `integer_as_continuous` unique values, it is treated as numeric. Defaults to 5. Set to TRUE to always treat integer predictors as continuous.

- For count regression models that use an offset term, use `offset = <value>` to fix the offset at a specific value. Or use `estimate = "average"`, to average predictions over the distribution of the offset (if appropriate).

**trend** A character indicating the name of the variable for which to compute the slopes. To get marginal effects at specific values, use `trend="<variable>"` along with the `by` argument, e.g. `by="<variable>=c(1, 3, 5)"`, or a combination of `by` and `length`, for instance, `by="<variable>"`, `length=30`. To calculate average marginal effects over a range of values, use `trend="<variable>=seq(1, 3, 0.1)"` (or similar) and omit the variable provided in `trend` from the `by` argument.

**ci** Confidence Interval (CI) level. Default to 0.95 (95%).

**estimate** The `estimate` argument determines how predictions are averaged ("marginalized") over variables not specified in `by` or `contrast` (non-focal predictors). It controls whether predictions represent a "typical" individual, an "average" individual from the sample, or an "average" individual from a broader population.

- "typical" (Default): Calculates predictions for a balanced data grid representing all combinations of focal predictor levels (specified in `by`). For non-focal numeric predictors, it uses the mean; for non-focal categorical predictors, it marginalizes (averages) over the levels. This represents a "typical" observation based on the data grid and is useful for comparing groups. It answers: "What would the average outcome be for a 'typical' observation?". This is the default approach when estimating marginal means using the *emmeans* package.
- "average": Calculates predictions for each observation in the sample and then averages these predictions within each group defined by the focal predictors. This reflects the sample's actual distribution of non-focal predictors, not a balanced grid. It answers: "What is the predicted value for an average observation in my data?"
- "population": "Clones" each observation, creating copies with all possible combinations of focal predictor levels. It then averages the predictions across these "counterfactual" observations (non-observed permutations) within each group. This extrapolates to a hypothetical broader population, considering "what if" scenarios. It answers: "What is the predicted response for the 'average' observation in a broader possible target population?" This approach entails more assumptions about the likelihood of different combinations, but can be more apt to generalize. This is also the option that should be used for **G-computation** (causal inference, see *Chatton and Rohrer 2024*). "counterfactual" is an alias for "population".

You can set a default option for the `estimate` argument via `options()`, e.g. `options(modelbased_estimate = "average")`.

Note following limitations:

- When you set `estimate` to "average", it calculates the average based only on the data points that actually exist. This is in particular important for two

or more focal predictors, because it doesn't generate a *complete* grid of all theoretical combinations of predictor values. Consequently, the output may not include all the values.

- Filtering the output at values of continuous predictors, e.g. `by = "x=1:5"`, in combination with `estimate = "average"` may result in returning an empty data frame because of what was described above. In such case, you can use `estimate = "typical"` or use the `newdata` argument to provide a data grid of predictor values at which to evaluate predictions.
- `estimate = "population"` is not available for `estimate_slopes()`.

transform	A function applied to predictions and confidence intervals to (back-) transform results, which can be useful in case the regression model has a transformed response variable (e.g., <code>lm(log(y) ~ x)</code> ). For Bayesian models, this function is applied to individual draws from the posterior distribution, before computing summaries. Can also be TRUE, in which case <code>insight::get_transformation()</code> is called to determine the appropriate transformation-function. Note that no standard errors are returned when transformations are applied.
p_adjust	The p-values adjustment method for frequentist multiple comparisons. For <code>estimate_slopes()</code> , multiple comparison only occurs for Johnson-Neyman intervals, i.e. in case of interactions with two numeric predictors (one specified in <code>trend</code> , one in <code>by</code> ). In this case, the "esarey" or "sup-t" options are recommended, but <code>p_adjust</code> can also be one of "none" (default), "hochberg", "hommel", "bonferroni", "BH", "BY", "fdr", "tukey", "sidak", or "holm". "sup-t" computes simultaneous confidence bands, also called sup-t confidence band (Montiel Olea & Plagborg-Møller, 2019).

## Examples

```
# Basic usage
model <- lm(Sepal.Width ~ Species, data = iris)
get_emcontrasts(model)

## Not run:
# Dealing with interactions
model <- lm(Sepal.Width ~ Species * Petal.Width, data = iris)
# By default: selects first factor
get_emcontrasts(model)
# Or both
get_emcontrasts(model, contrast = c("Species", "Petal.Width"), length = 2)
# Or with custom specifications
get_emcontrasts(model, contrast = c("Species", "Petal.Width=c(1, 2)"))
# Or modulate it
get_emcontrasts(model, by = "Petal.Width", length = 4)

## End(Not run)

model <- lm(Sepal.Length ~ Species + Petal.Width, data = iris)

# By default, 'by' is set to "Species"
get_emmeans(model)
```

```

## Not run:
# Overall mean (close to 'mean(iris$Sepal.Length)')
get_emmeans(model, by = NULL)

# One can estimate marginal means at several values of a 'modulate' variable
get_emmeans(model, by = "Petal.Width", length = 3)

# Interactions
model <- lm(Sepal.Width ~ Species * Petal.Length, data = iris)

get_emmeans(model)
get_emmeans(model, by = c("Species", "Petal.Length"), length = 2)
get_emmeans(model, by = c("Species", "Petal.Length = c(1, 3, 5)"), length = 2)

## End(Not run)

## Not run:
model <- lm(Sepal.Width ~ Species * Petal.Length, data = iris)

get_emtrends(model)
get_emtrends(model, by = "Species")
get_emtrends(model, by = "Petal.Length")
get_emtrends(model, by = c("Species", "Petal.Length"))

## End(Not run)

model <- lm(Petal.Length ~ poly(Sepal.Width, 4), data = iris)
get_emtrends(model)
get_emtrends(model, by = "Sepal.Width")

model <- lm(Sepal.Length ~ Species + Petal.Width, data = iris)

# By default, 'by' is set to "Species"
get_marginalmeans(model)

# Overall mean (close to 'mean(iris$Sepal.Length)')
get_marginalmeans(model, by = NULL)

## Not run:
# One can estimate marginal means at several values of a 'modulate' variable
get_marginalmeans(model, by = "Petal.Width", length = 3)

# Interactions

get_marginaltrends(model, trend = "Petal.Length", by = c("Species", "Petal.Length"))
```

---

modelbased-options      *Global options from the modelbased package*

---

## Description

Global options from the modelbased package

## Global options to set defaults for function arguments

### For calculating marginal means

- `options(modelbased_backend = <string>)` will set a default value for the backend argument and can be used to set the package used by default to calculate marginal means. Can be "marginaleffects" or "emmeans".
- `options(modelbased_estimate = <string>)` will set a default value for the estimate argument, which modulates the type of target population predictions refer to.
- `options(modelbased_integer = <value>)` will set the minimum number of unique values in an integer predictor to treat that predictor as a "discrete integer" or as continuous. If the integer has more than `modelbased_integer` unique values, it is treated as continuous. Set to TRUE to always treat integer predictors as continuous.

### For printing

- `options(modelbased_select = <string>)` will set a default value for the select argument and can be used to define a custom default layout for printing.
- `options(modelbased_include_grid = TRUE)` will set a default value for the `include_grid` argument and can be used to include data grids in the output by default or not.
- `options(modelbased_full_labels = FALSE)` will remove redundant (duplicated) labels from rows.
- `options(easystats_display_format = <value>)` will set the default format for the `display()` methods. Can be one of "markdown", "html", or "tt". See [display.estimate\\_contrasts\(\)](#) for details.

### For plotting

- `options(modelbased_join_dots = <logical>)` will set a default value for the `join_dots`.
- `options(modelbased_numeric_as_discrete = <number>)` will set a default value for the `modelbased_numeric_as_discrete` argument. Can also be FALSE.
- `options(modelbased_ribbon_alpha = <number>)` will set a default value for the alpha argument of the ribbon geom. Should be a number between 0 and 1.

- `options(modelbased_tinyplot_dodge = <number>)` will set a default value for the `dodge` argument (spacing between geoms) when using `tinyplot::plt()`. Should be a number between 0 and 1.

---

plot.estimate\_predicted

*Automated plotting for 'modelbased' objects*

---

## Description

Most **modelbased** objects can be visualized using either the `plot()` function, which internally calls the `visualisation_recipe()` function and relies on `{ggplot2}`. There is also a `tinyplot()` method, which uses the `{tinyplot}` package and relies on the core R graphic system. See the examples below for more information and examples on how to create and customize plots.

The plotting works by mapping any predictors from the `by` argument to the x-axis, colors, alpha (transparency) and facets. Thus, the appearance of the plot depends on the order of the variables that you specify in the `by` argument. For instance, the plots corresponding to `estimate_relation(model, by=c("Species", "Sepal.Length"))` and `estimate_relation(model, by=c("Sepal.Length", "Species"))` will look different.

The automated plotting is primarily meant for convenient visual checks, but for publication-ready figures, we recommend re-creating the figures using the `{ggplot2}` package directly.

## Usage

```
## S3 method for class 'estimate_predicted'
plot(x, ...)

## S3 method for class 'estimate_means'
plot(x, ...)

## S3 method for class 'estimate_means'
tinyplot(
  x,
  type = NULL,
  dodge = NULL,
  show_data = FALSE,
  numeric_as_discrete = NULL,
  ...
)

## S3 method for class 'estimate_predicted'
visualisation_recipe(
  x,
  show_data = FALSE,
  show_residuals = FALSE,
  point = NULL,
```

```

    line = NULL,
    pointrange = NULL,
    ribbon = NULL,
    facet = NULL,
    grid = NULL,
    join_dots = NULL,
    numeric_as_discrete = NULL,
    ...
)

## S3 method for class 'estimate_slopes'
visualisation_recipe(
  x,
  line = NULL,
  pointrange = NULL,
  ribbon = NULL,
  facet = NULL,
  grid = NULL,
  ...
)

## S3 method for class 'estimate_grouplevel'
visualisation_recipe(
  x,
  line = NULL,
  pointrange = NULL,
  ribbon = NULL,
  facet = NULL,
  grid = NULL,
  ...
)

```

### Arguments

<code>x</code>	A modelbased object.
<code>...</code>	Arguments passed from <code>plot()</code> to <code>visualisation_recipe()</code> , or to <code>tinypplot()</code> if you use that method.
<code>type</code>	The type of <code>tinypplot</code> visualization. It is recommended that users leave as <code>NULL</code> (the default), in which case the plot type will be determined automatically by the underlying modelbased object.
<code>dodge</code>	Dodge value for grouped plots. If <code>NULL</code> (the default), then the dodging behavior is determined by the number of groups and <code>getOption("modelbased_tinypplot_dodge")</code> .
<code>show_data</code>	Logical, if <code>TRUE</code> , display the "raw" data as a background to the model-based estimation. This argument will be ignored for plotting objects returned by <code>estimate_slopes()</code> or <code>estimate_grouplevel()</code> .
<code>numeric_as_discrete</code>	Maximum number of unique values in a numeric predictor to treat that predictor as discrete. Defaults to 8. Numeric predictors are usually mapped to a contin-

uous color scale, unless they have only few unique values. In the latter case, numeric predictors are assumed to represent "categories", e.g. when only the mean value and +/- 1 standard deviation around the mean are chosen as representative values for that predictor. Use FALSE to always use continuous color scales for numeric predictors. It is possible to set a global default value using options(), e.g. options(modelbased\_numeric\_as\_discrete = 10).

show_residuals	Logical, if TRUE, display residuals of the model as a background to the model-based estimation. Residuals will be computed for the predictors in the data grid, using <code>residualize_over_grid()</code> .
point, line, pointrange, ribbon, facet, grid	Additional aesthetics and parameters for the geoms (see customization example).
join_dots	Logical, if TRUE (default) and for categorical focal terms in by, dots (estimates) are connected by lines, i.e. plots will be a combination of dots with error bars and connecting lines. If FALSE, only dots and error bars are shown. It is possible to set a global default value using options(), e.g. options(modelbased_join_dots = FALSE).

## Details

There are two options to remove the confidence bands or errors bars from the plot. To remove error bars, simply set the pointrange geom to point, e.g. `plot(..., pointrange = list(geom = "point"))`. To remove the confidence bands from line geoms, use `ribbon = "none"`.

## Value

An object of class `visualisation_recipe` that describes the layers used to create a plot based on `{ggplot2}`. The related `plot()` method is in the `{see}` package.

## Global Options to Customize Plots

Some arguments for `plot()` can get global defaults using `options()`:

- `modelbased_join_dots`: `options(modelbased_join_dots = <logical>)` will set a default value for the `join_dots`.
- `modelbased_numeric_as_discrete`: `options(modelbased_numeric_as_discrete = <number>)` will set a default value for the `modelbased_numeric_as_discrete` argument. Can also be FALSE.
- `modelbased_ribbon_alpha`: `options(modelbased_ribbon_alpha = <number>)` will set a default value for the `alpha` argument of the `ribbon` geom. Should be a number between 0 and 1.
- `modelbased_tinyplot_dodge`: `options(modelbased_tinyplot_dodge = <number>)` will set a default value for the `dodge` argument (spacing between geoms) when using `tinyplot::plt()`. Should be a number between 0 and 1.

**Examples**

```

# =====
# tinyplot
# =====

library(tinyplot)
data(efc, package = "modelbased")
efc <- datawizard::to_factor(efc, c("e16sex", "c172code", "e42dep"))

---

pool\_contrasts                      *Pool contrasts and comparisons from estimate\_contrasts()*

---

## Description

This function "pools" (i.e. combines) multiple `estimate_contrasts` objects, returned by `estimate_contrasts()`, in a similar fashion as `mice::pool()`.

## Usage

```
pool_contrasts(x, ...)
```

## Arguments

`x`                      A list of `estimate_contrasts` objects, as returned by `estimate_contrasts()`.  
`...`                    Currently not used.

## Details

Averaging of parameters follows Rubin's rules (*Rubin, 1987, p. 76*).

## Value

A data frame with pooled comparisons or contrasts of predictions.

## References

Rubin, D.B. (1987). *Multiple Imputation for Nonresponse in Surveys*. New York: John Wiley and Sons.

## Examples

```
data("nhanes2", package = "mice")
imp <- mice::mice(nhanes2, printFlag = FALSE)
comparisons <- lapply(1:5, function(i) {
  m <- lm(bmi ~ age + hyp + chl, data = mice::complete(imp, action = i))
  estimate_contrasts(m, "age")
})
pool_contrasts(comparisons)
```

---

pool\_predictions

*Pool Predictions and Estimated Marginal Means*

---

## Description

This function "pools" (i.e. combines) multiple `estimate_means` objects, in a similar fashion as `mice::pool()`.

## Usage

```
pool_predictions(x, transform = NULL, ...)
```

```
pool_slopes(x, transform = NULL, ...)
```

## Arguments

- |           |   |
|-----------|---|
| x         | A list of <code>estimate_means</code> objects, as returned by <code>estimate_means()</code> , or <code>estimate_predicted</code> objects, as returned by <code>estimate_relation()</code> and related functions. For <code>pool_slopes()</code> , must be a list of <code>estimate_slopes</code> objects, as returned by <code>estimate_slopes()</code> .   |
| transform | A function applied to predictions and confidence intervals to (back-) transform results, which can be useful in case the regression model has a transformed response variable (e.g., $\text{lm}(\log(y) \sim x)$ ). For Bayesian models, this function is applied to individual draws from the posterior distribution, before computing summaries. Can also be <code>TRUE</code> , in which case <code>insight::get_transformation()</code> is called to determine the appropriate transformation-function. Note that no standard errors are returned when transformations are applied. |
| ...       | Currently not used.   |

**Details**

Averaging of parameters follows Rubin's rules (*Rubin, 1987, p. 76*). Pooling is applied to the predicted values and based on the standard errors as they are calculated in the `estimate_means` or `estimate_predicted` objects provided in `x`. For objects of class `estimate_means`, the predicted values are on the response scale by default, and standard errors are calculated using the delta method. Then, pooling estimates and calculating standard errors for the pooled estimates based on Rubin's rule is carried out. There is no back-transformation to the link-scale of predicted values before applying Rubin's rule.

**Value**

A data frame with pooled predictions.

**References**

Rubin, D.B. (1987). *Multiple Imputation for Nonresponse in Surveys*. New York: John Wiley and Sons.

**Examples**

```
# example for multiple imputed datasets
data("nhanes2", package = "mice")
imp <- mice::mice(nhanes2, printFlag = FALSE)

# estimated marginal means
predictions <- lapply(1:5, function(i) {
  m <- lm(bmi ~ age + hyp + chl, data = mice::complete(imp, action = i))
  estimate_means(m, "age")
})
pool_predictions(predictions)

# estimated slopes (marginal effects)
slopes <- lapply(1:5, function(i) {
  m <- lm(bmi ~ age + hyp + chl, data = mice::complete(imp, action = i))
  estimate_slopes(m, "chl")
})
pool_slopes(slopes)
```

---

puppy\_love

*More puppy therapy data*

---

**Description**

Fictitious data related to whether puppy therapy works when you adjust for a person's love of puppies, taken from the `{discovr}` package (Field 2025)

**Details**

Following variables are included in the dataset:

- ‘id’: Participant id
- dose: Treatment group to which the participant was randomly assigned (No puppies (control), 15 minutes of puppy therapy, 30 minutes of puppy therapy)
- happiness: Self-reported happiness from 0 (as unhappy as I can possibly imagine being) to 10 (as happy as I can possibly imagine being)
- puppy\_love: Self-reported love of puppies from 0 (I am a weird person who hates puppies, please be deeply suspicious of me) to 7 (puppies are the best thing ever, one day I might marry one)

For further details, see `?discover::puppy_love`.

**References**

---

`residualize_over_grid` *Compute partial residuals from a data grid*

---

**Description**

This function computes partial residuals based on a data grid, where the data grid is usually a data frame from all combinations of factor variables or certain values of numeric vectors. This data grid is usually used as `newdata` argument in `predict()`, and can be created with `insight::get_datagrid()`.

**Usage**

```
residualize_over_grid(grid, model, ...)

## S3 method for class 'data.frame'
residualize_over_grid(grid, model, predictor_name, ...)
```

**Arguments**

<code>grid</code>	A data frame representing the data grid, or an object of class <code>estimate_means</code> or <code>estimate_predicted</code> , as returned by the different <code>estimate_*()</code> functions.
<code>model</code>	The model for which to compute partial residuals. The data grid <code>grid</code> should match to predictors in the model.
<code>...</code>	Currently not used.
<code>predictor_name</code>	The name of the focal predictor, for which partial residuals are computed.

**Value**

A data frame with residuals for the focal predictor.

## Partial Residuals

For **generalized linear models** (glms), residualized scores are computed as `inv.link(link(Y) + r)` where  $Y$  are the predicted values on the response scale, and  $r$  are the *working* residuals.

For (generalized) linear **mixed models**, the random effect are also partialled out.

## References

Fox J, Weisberg S. Visualizing Fit and Lack of Fit in Complex Regression Models with Predictor Effect Plots and Partial Residuals. *Journal of Statistical Software* 2018;87.

## Examples

```
set.seed(1234)
x1 <- rnorm(200)
x2 <- rnorm(200)
# quadratic relationship
y <- 2 * x1 + x1^2 + 4 * x2 + rnorm(200)

d <- data.frame(x1, x2, y)
model <- lm(y ~ x1 + x2, data = d)

pr <- estimate_means(model, c("x1", "x2"))
head(residualize_over_grid(pr, model))
```

---

smoothing

*Smoothing a vector or a time series*

---

## Description

Smoothing a vector or a time series. For data.frames, the function will smooth all numeric variables stratified by factor levels (i.e., will smooth within each factor level combination).

## Usage

```
smoothing(x, method = "loess", strength = 0.25, ...)
```

## Arguments

<code>x</code>	A numeric vector.
<code>method</code>	Can be "loess" (default) or "smooth". A loess smoothing can be slow.
<code>strength</code>	This argument only applies when <code>method = "loess"</code> . Degree of smoothing passed to <code>span</code> (see <code>loess()</code> ).
<code>...</code>	Arguments passed to or from other methods.

## Value

A smoothed vector or data frame.

**Examples**

```
x <- sin(seq(0, 4 * pi, length.out = 100)) + rnorm(100, 0, 0.2)
plot(x, type = "l")
lines(smoothing(x, method = "smooth"), type = "l", col = "blue")
lines(smoothing(x, method = "loess"), type = "l", col = "red")

x <- sin(seq(0, 4 * pi, length.out = 10000)) + rnorm(10000, 0, 0.2)
plot(x, type = "l")
lines(smoothing(x, method = "smooth"), type = "l", col = "blue")
lines(smoothing(x, method = "loess"), type = "l", col = "red")
```

---

`zero_crossings`*Find zero-crossings and inversion points*

---

**Description**

Find zero crossings of a vector, i.e., indices when the numeric variable crosses 0. It is useful for finding the points where a function changes by looking at the zero crossings of its derivative.

**Usage**

```
zero_crossings(x)
```

```
find_inversions(x)
```

**Arguments**

`x` A numeric vector.

**Value**

Vector of zero crossings or points of inversion.

**See Also**

Based on the `uniroot.all` function from the `rootSolve` package.

**Examples**

```
x <- sin(seq(0, 4 * pi, length.out = 100))
# plot(x, type = "b")

modelbased::zero_crossings(x)
modelbased::find_inversions(x)
```
